## Abstract

We present results from molecular dynamics simulations that examine microscopic characteristics of mixtures combining acetonitrile(ACN) and dimethylsulfoxide(DMSO) at the vicinity of liquid/air and liquid/graphene interfaces. In the the former interfaces, our simulations reveal a clear propensity of ACN to lie adjacent to the vapor phase at all concentrations. A simple model based on the consideration of a chemical equilibrium between bulk and surface states and the liquid/vapor surface tensions of the pure solvents was found to be adequate to reproduce simulation results. Orientational correlations at the interface showed a mild tendency for dipolar alignments pointing towards the vapor phase in ACN rich solutions; contrasting, in DMSO-rich mixtures, the preferential orientations looked mostly parallel to the interface. Close to graphene plates, the local scenarios reverse and local concentrations of DMSO are larger than the one observed in the bulk. This preferential wall-solvation was found to be more marked as we included an additional Coulomb coupling between the graphene walls and the mixture. Dynamical results reveal that the characteristic timescales describing orientational relaxations and residence times at the interfaces stretch as the concentration of ACN diminishes. For liquid/air interfaces residence times for ACN were found to be larger than those for DMSO, despite that, in the bulk, ACN diffuses faster than DMSO. A classical treatment for the predictions of the C-H stretching band of the IR peaks the bulk and at the interfaces reveal shifts which agree with experimental measurements.

## Introduction

Acetonitrile (ACN) and dimethylsulfoxide (DMSO) represent prototypical examples of aprotic polar solvents with practical applications in areas as diverse as cryoprotection,<sup>1</sup> liquid chromatography,<sup>2</sup> energy storage devices,<sup>3</sup> medicinal chemistry,<sup>4</sup> atmospheric sciences,<sup>5</sup> to cite a few relevant examples. Based on their common aprotic character and the similarities between their corresponding dipole moments, 3.96 D(ACN) versus 3.92 D(DMSO) and dielectric constants (both close to  $\sim 40$ ), one would be tempted to conclude that chemical

reactivity in these two media should not differ in a substantial fashion. However, in fact, the latter statement is only partially true. For example, the experimentally reported dissociation constant of HCl in DMSO is practically six orders of magnitude larger than the one observed in ACN.<sup>6,7</sup> Computer simulations have demonstrated that these differences can be ascribed to modifications in the ionic solvation structures, which lead to much more stable solvent-separated-ion-pairs in DMSO.<sup>8</sup> Clearly, the physical interpretations of these subtleties require much more detailed analyses that go beyond the simple consideration of the dipole moments or the collective polarization responses of the two species.

Mixtures combining these two solvents open possibilities for “intermediate” solvation environments between the limiting, pure liquid, structures. However, in many cases, the resulting scenarios deviate considerably from the ideal-mixture behaviors. In a recent paper, we reported a molecular dynamics analysis of solvation of simple ionic species in these mixtures that showed a marked asymmetry in the solvation of  $\text{Li}^+\text{-Cl}^-$  ion pairs, with a clear preference of DMSO for cationic solvation at practically all concentrations.<sup>9</sup> These differences, in turn, were also registered in conductivity results that showed pronounced changes in ionic mobilities in ACN-rich solutions with concentrations as high as  $x_{\text{ACN}} \sim 0.95$ .<sup>10</sup> All these non-idealities contrast sharply with the results reported by Bernardi et al.<sup>11</sup> for the internal energies of the mixtures which show only mild positive deviations, and with the experimental molar volumes, which follow a linear dependence with the individual concentrations.<sup>12</sup>

Microscopic descriptions of these mixtures in the vicinity of interfaces incorporate additional ingredients to these, already complex, bulk solvation structures; most notably are those related to the strong gradients in the intermolecular forces that prevail in these environments. The behavior of mixtures involving polar aprotic solvents at liquid/vapor and liquid/solid interfaces has received considerable attention in recent years; however, these studies have focused on combinations involving, almost exclusively, water(W) as cosolvent.<sup>13-23</sup> The specific case of ACN-W mixtures is particularly enlightening since many characteristics of the prevailing structures of the liquid mixtures could be rationalized invoking the well doc-

umented hydrophobicity of the water/air interface,<sup>24-26</sup> contraposed with the hydrophilic character of hydroxylated silica surfaces. The latter characteristics clearly control the gross features of concentration fluctuations at the interfaces which, in some cases, may even lead to structures compatible with microscopic demixing phenomena.<sup>13,19,27</sup> Unfortunately, similar interpretations performed on mixtures of aprotic solvents at interfaces have a much more limited scope.

These limitations underline the main motivation of the present work, in which we examine microscopic characteristics of ACN/DMSO mixtures at liquid/air and liquid/graphene interfaces, using molecular dynamics techniques. Our study includes a detailed analysis of concentration fluctuations at the different interfaces along with the corresponding orientational correlations. For the particular case of graphene, we have explored the modifications operated at the interfaces by the addition of Coulomb coupling between the liquid phase and the walls to gain insights about solvation structures of these mixtures at the vicinity of charged electrodes. This information might have potential relevance in the design of lithium-ion batteries.<sup>28</sup> On the dynamical side, we focused attention on two relevant dynamical modes. The first one corresponded to diffusive motions perpendicular to the interfaces, interpreted by the corresponding residence times. In addition, we also investigated relaxations of orientational motions. The paper concludes with a classical analysis of the characteristics of the shifts operated in the C-H stretching bands of the corresponding IR spectra at the surfaces, by comparing them with those obtained from simulations in the bulk.

The organization of the paper is as follows: Details of the model and technical details of the simulations are provided in Section II. The central sections, III and IV, include results for equilibrium and dynamical properties, respectively. In the final section, we summarize the main conclusions of the work.

# Models and technical details of the simulations

## Liquid/air interfaces

Computer simulations were performed on ACN/DMSO mixtures, with global concentrations  $x_{\text{ACN}} = 0.25, 0.5$  and  $0.75$ . As references, a few test runs were also undertaken for pure liquid phases. Our procedure started by performing equilibration runs on fully periodic, bulk phases, at  $T = 298$  K. The lengths of the original rectangular cells were fixed at  $L_x = L_y = 40$  Å and  $L_z = 50$  Å, whereas the numbers of molecules of each species,  $N_\alpha$  ( $\alpha = \text{ACN}, \text{DMSO}$ ), were adjusted so as to bring the densities of the mixtures in agreement with the experimental results reported in Ref.[12]. Following these initial stages, we enlarged  $L_z$  up to  $150$  Å and performed additional canonical runs for about  $\sim 100 - 200$  ps, using a Nosé-Hoover thermostat.<sup>29,30</sup> With this procedure, we obtained stable liquid/vapor interfaces showing practically no evaporation episodes.

All molecules were modeled as fully flexible collections of atoms. For DMSO, we adopted the *FS* potential reported in Ref.[31] whereas, for ACN, we implemented the *C* model developed by Nikitin et al.<sup>32</sup> To evaluate cross interactions we resorted to the classical arithmetic and geometric means for length and energy parameters describing Lennard-Jones, dispersive interactions. This combination of force fields provided liquid mixtures showing no meaningful modifications in pair correlation functions and no evidence of phase separation artifacts along time spans of the order of a few tens of nanoseconds.

Short-range intermolecular forces were computed using a cut-off distance of  $13$  Å, while the long nature of the electrostatic forces was treated by implementing Ewald sums, using a particle mesh method. Appropriate sampling of equilibrium properties required of the order of  $\sim 3-5$ , statistically independent, canonical runs, lasting typically  $\sim 20$  ns each. On the other hand, dynamical properties were computed from microcanonical runs of similar duration. All simulations were performed using the NAMD package.<sup>33</sup>

## Liquid/graphene interfaces

Mixtures confined within graphene walls were prepared following a protocol similar to the one described previously. In this case, the mixtures were confined within two graphene plates, held fixed at  $z = \pm 40 \text{ \AA}$ , with planar surfaces perpendicular to the  $z$  axis. The plates consisted of three rigid atomic layers containing 448 atoms each, with closest interatomic distances set at  $1.42 \text{ \AA}$ . The linear dimensions of the sheets were  $34.08 \text{ \AA} \times 34.43 \text{ \AA}$ . As a distinctive feature, at each value of  $x_{\text{ACN}}$ , we started by performing a series of simulation runs in which, by trial and error, the numbers of molecules of each species were fixed so as to bring the local densities at the  $z \sim 0$ , “bulk” region in agreement with the corresponding experimental values. In doing so, we found local molar fractions  $x_{\text{ACN}}^{\text{blk}}$  that deviated at most in 1-2% from the preset  $x_{\text{ACN}}$  values. Two kinds of simulation experiments, differing in the characteristics of liquid/plates interactions were undertaken: in the first one, solvent-graphene interactions were considered exclusively of the Lennard-Jones type. The parametrization of the energy and length parameters for C-atoms in the plates was taken from the CHARMM27 library:<sup>34</sup>  $\sigma_{\text{C}} = 3.55 \text{ \AA}$ ,  $\epsilon_{\text{C}} = 0.07 \text{ kcal mol}^{-1}$ . In order to explore the modifications observed in the liquid mixtures in the vicinity of charged electrodes, we also performed a second set of simulations in which total charges  $Q = \pm 4.48e$  were uniformly distributed across the atomic positions of the layers directly exposed to the mixtures, giving rise to global charge densities of  $\sigma_q \sim \pm 6.1 \text{ \mu C cm}^{-2}$ . Recent studies<sup>35</sup> have demonstrated limitations in descriptions based on uniform charge distributions, in contraposition with more realistic ones that impose the correct electrostatic, constant voltage, boundary conditions.<sup>36</sup> Anyhow, subsequent analyses<sup>37</sup> have shown that these inadequacies become relevant for charge densities greater than the one investigated here.

# Equilibrium Results

## Liquid/air interfaces

The starting point of our analysis will be the examination of local density fluctuations associated with the two species in the vicinity of the liquid/air interfaces. In particular, we will focus attention on  $g_\alpha(z)$ , namely:

$$g_\alpha(z) = \frac{1}{\rho_\alpha^{blk} L_x L_y} \sum_{i=1}^{N_\alpha} \langle \delta(Z_i^\alpha - Z_{\text{CM}} - z) \rangle \quad ; \quad (1)$$

where  $\langle \dots \rangle$  denotes an equilibrium ensemble average; in addition,  $Z_i^\alpha$  and  $Z_{\text{CM}}$  correspond to the  $z$ -coordinates of the center of mass of the  $i$ th molecule of species  $\alpha$  in the mixture and the center of mass of the slab, respectively. In the same expression,  $\rho_\alpha^{blk}$  represents the bulk density of component  $\alpha$ ; the latter values were adjusted so that all  $g_\alpha$  plots level off at unity for  $z \sim 0$ . In what follows, we will show that, due to the characteristics of the local concentration fluctuations at the interfaces, the values of  $\rho_{\text{ACN}}^{blk}$  were found to be somewhat smaller than those estimated from the global stoichiometry of the mixtures (see entries listed in column 2 of Table 1). These differences are due to finite size effects that scale as  $V^{-1/3}$  and, consequently, should progressively disappear in larger systems.

Results for  $g_\alpha(z)$  for different mixtures are depicted in Fig. 1; as references, we have also included results for liquid/air interfaces of pure-solvent slabs. As we move from the vapor toward the liquid phase, DMSO plots present gradual increments in agreement with the usual “hyperbolic-tangent profiles”, with widths that become wider as  $x_{\text{DMSO}}$  diminishes. Contrasting, the ACN profiles look shifted towards the vapor phase and exhibit net enhancements of the local densities at the interface, compared to the bulk values. These increments become more marked as the global concentration of ACN diminishes, reaching  $g_{\text{ACN}}(z = 23) \sim 1.8$  for the  $x_{\text{ACN}} = 0.25$  mixture.

The profiles depicted in Fig. 1 represent thermally averaged results that do not allow for

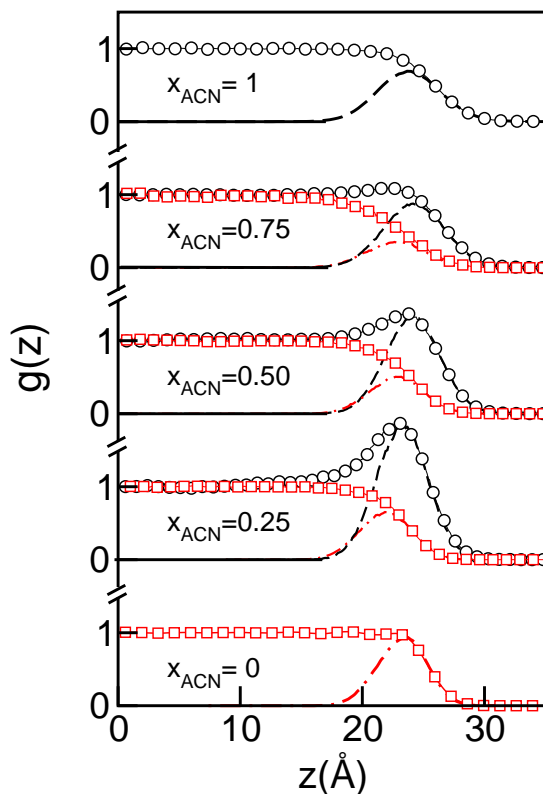

Figure 1: Local densities of ACN (open circles) and DMSO (open squares) for different mixtures at the liquid/air interfaces. Also shown are results for densities of molecules lying at the interface. ACN(dashed black lines) and DMSO (dash-dotted red lines).

a clear identification of the modifications operated in the number and in the identity of the tagged molecules lying at the instantaneous interfaces. Different methods, mostly based on geometrical considerations, have been devised to keep track of interfacial molecules.<sup>18,38–42</sup> For the present case, we found it practical to resort to a strategy based on probe particles,<sup>22,23,43,44</sup> which can be implemented in multicomponent systems in a straightforward fashion. Briefly, the algorithm involves approaching a test sphere along the  $z$ -direction, from the vapor toward the liquid phases, keeping its  $x$  and  $y$  coordinates fixed at a series of grid points spanning the  $x$ - $y$  plane. The approach is interrupted once the distance between the test sphere and a tagged site in the liquid phase attains a low-threshold value. With this procedure, a molecule was considered as lying at the interface if at least one of its atomic sites was intercepted by the test sphere. In the present case, the grid comprised a total of

equally spaced,  $40 \times 40$  points, whereas the threshold distances of encounter were computed from arithmetic means involving the Lennard-Jones length parameters of the tagged sites and the diameter of the test sphere that was set to  $4 \text{ \AA}$ . The interested reader is referred to Ref.[43] for a comprehensive discussion about appropriate choices of these parameters.

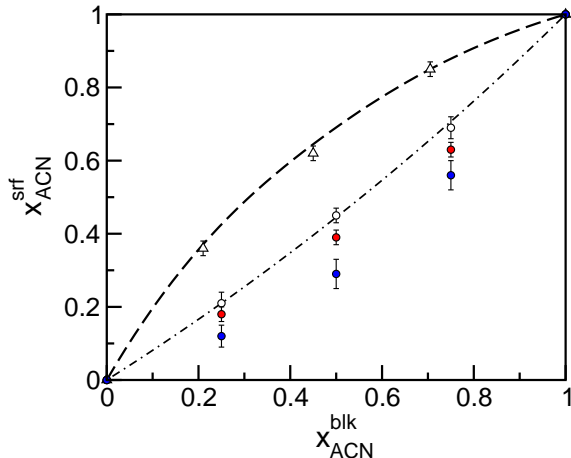

Figure 2: Surface local concentration for different mixtures: Liquid/air interfaces (triangles); liquid/graphene interfaces ( $Q = 0$ : open circles;  $Q > 0$ : red circles;  $Q < 0$ : blue circles). The dashed and dot-dashed lines correspond to predictions from Eq. 2 (see text).

Local densities corresponding ACN and DMSO surface molecules, normalized in a similar fashion to the one implemented in the computation of the  $g_\alpha(z)$  profiles, appear in Fig. 1 with black-dashed and with red-dotted-dashed lines, respectively. In all cases, the plots look reasonably Gaussian-like, with widths of the order of  $\sim 2 \text{ \AA}$ . ACN distributions look  $\sim 1 \text{ \AA}$  shifted towards the vapor phase, compared to the DMSO counterparts and are centered at positions that practically coincide with those of the maxima of the  $g_{ACN}(z)$  (open circles). DMSO density curves are centered close to the corresponding Gibbs dividing surfaces, computed invoking the usual mid-point criterion between the 90%-10% liquid bulk densities.

The integrals over the Gaussian profiles provide estimates for the local compositions at the slab surfaces  $x_\alpha^{surf}$ . In Fig. 2 we present results for surface versus bulk compositions. Typically, these interfaces can accommodate a total of  $65 - 75$  molecules, yielding results for the area per molecule of the order of  $\bar{A} \sim 23 \text{ \AA}^2$  (see values listed in columns 6 of Table 1).

Similar estimates have been reported for DMSO-interface in Table 2 of Ref.[18]. The plot shown in Fig. 2 (triangles) reveals clear enhancements of the local concentration of ACN at the surface, attaining a value  $\sim 70\%$  larger than the one observed in the bulk for the  $x_{\text{ACN}} = 0.25$  mixture (see column 4 of Table 1).

**Table 1: Local concentrations of ACN/DMSO mixtures in the vicinity of different interfaces.**

$x_{\text{ACN}}$	$x_{\text{ACN}}^{\text{blk}}$	$x_{\text{ACN}}^{\text{srf}}$	$x_{\text{ACN}}^{\text{srf}}/x_{\text{ACN}}^{\text{blk}}$	$\bar{A}(\text{\AA}^2)$
a. liquid/air interfaces				
0.0	0.0	0.00	–	25.3
0.25	0.21	0.36	1.7	23.5
0.50	0.45	0.63	1.4	22.3
0.75	0.71	0.85	1.2	21.5
1.0	1.00	1.00	1.0	20.8
b. liquid/graphene interfaces				
0.25	0.25	0.21	0.84	25.4
0.50	0.50	0.45	0.90	23.4
0.75	0.75	0.69	0.92	22.6

The observed propensity of ACN to lie at the surface can be further rationalized invoking a simple model in which the surface layer and the adjacent bulk environment are considered as two phases in equilibrium. By establishing that the chemical potential of each species at the bulk and at surface are equal, a straightforward mathematical treatment leads to the following approximate expression:<sup>45,46</sup>

$$x_{\text{ACN}}^{\text{srf}} \sim \frac{x_{\text{ACN}}^{\text{blk}}}{\omega(1 - x_{\text{ACN}}^{\text{blk}}) + x_{\text{ACN}}^{\text{blk}}} \quad (2)$$

with

$$\omega = \exp \left[ \frac{(\gamma_{\text{ACN}}^{\text{lv}} - \gamma_{\text{DMSO}}^{\text{lv}})\bar{A}}{k_B T} \right] . \quad (3)$$

In the previous expression,  $\gamma_\alpha^{lv}$  represents the liquid/vapor surface tension of the pure component  $\alpha$  and  $\bar{A}$  denotes the mean surface area per molecule in the mixture. Two basic approximations are involved in the derivation of Eq.2: (i) the first one establishes that the ratio between the activity coefficients of each component in the bulk and at the surface are similar, so that the ratio of activities can be approximated by the ratio of the corresponding molar fractions, namely:

$$a_\alpha^{srf} / a_\alpha^{blk} \sim x_\alpha^{srf} / x_\alpha^{blk} \quad ; \quad (4)$$

(ii) the second one considers that the areas per molecule of each species are also comparable, i.e.  $\bar{A}_{\text{DMSO}} \sim \bar{A}_{\text{ACN}} \sim \bar{A}$  which, in the present case, holds within  $\sim 5\%$  differences. Note that, according to Eq. 2, the ACN preference to lie at surface is controlled by the  $\omega$  term, i.e. the Boltzmann factor involving the difference between the surface tensions of the two components; this underlies the well known physical interpretation of  $\gamma_\alpha^{lv}$  in terms of the reversible work per unit of area required to bring  $\alpha$ -molecules from the bulk to the surface. Results for  $x_{\text{ACN}}^{srf}$  obtained from Eq. 2 are also shown in Fig. 2 (dashed line). They were computed using the experimental values of  $\gamma_{\text{ACN}}^{lv} = 28.5 \text{ erg cm}^{-2}$  and  $\gamma_{\text{DMSO}}^{lv} = 42.8 \text{ erg cm}^{-2}$  at  $T = 298 \text{ K}$  reported in Ref.[47], and assuming a single value of  $\bar{A} = 23 \text{ \AA}^2$ . Given the simplicity of the arguments involved in the derivation of the approximate Eq. 2, the degree of agreement is remarkable, although we cannot discard that it might also be partially fortuitous.

We will now move to the examination of local polarization fluctuations in the vicinity of the free interfaces. The most direct route to gain insight about these fluctuations involves the computation of distribution functions of the type:

$$P_\mu^\alpha(\cos \theta) = \frac{1}{N_\alpha^{srf}} \sum_{i=1}^{N_\alpha^{srf}} \langle \delta(\cos \theta_i - \cos \theta) \rangle_{srf} \quad ; \quad (5)$$

with

$$\cos \theta_i = \frac{\boldsymbol{\mu}_i^\alpha \cdot \hat{\mathbf{z}}}{|\boldsymbol{\mu}_i^\alpha|} \quad . \quad (6)$$

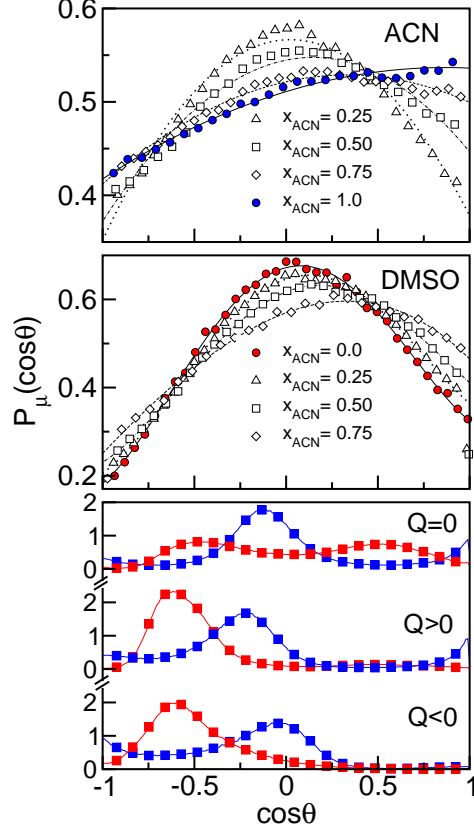

Figure 3: Polarization distributions at different interfaces. Top and middle panels contain results for ACN and DMSO for liquid-mixture/air interfaces: Bottom panel: distribution for dipolar orientations at liquid/graphene interfaces for an  $x_{\text{ACN}} = 0.5$  mixture. Red and blue squares correspond to results for DMSO and ACN, respectively.

In the previous equations,  $\mu_i^\alpha$  represents the dipole moment of the  $i$ th molecule of species  $\alpha$ ;  $\hat{\mathbf{z}}$ , a unit vector along the  $z$ -direction and  $\langle \dots \rangle_{srf}$  denotes a sampling restricted to the  $N_\alpha^{sfr}$  molecules lying at the interface. Results for  $P_\mu^{\text{ACN}}(\cos \theta)$  appear in the top panel of Fig. 3. All distributions show broad profiles, with a mild tendency favoring dipolar orientations pointing out, towards the gas phases. This tendency is less marked as the concentration of ACN decreases; note that for the  $x_{\text{ACN}} = 0.25$  case, the dipolar distribution looks practically symmetric with respect to  $\cos \theta = 0$ . In passing, we would like to comment on some differences between the  $x_{\text{ACN}} = 1$  results presented here and those shown in Fig. 2 of Ref. [48] and in Fig. 5(b) of Ref. [49]. These discrepancies can be ascribed to the fact that, in the latter cases, the samplings were restricted to external layers with widths comparable

to the size of the ACN molecule; under these circumstances “over counted” dipoles from molecules lying at adjacent regions may introduce apparent discrepancies in distributions obtained with different atomic locations.<sup>49</sup> Distributions for surface polarization for DMSO are shown in the middle panel of Fig. 3. At a qualitative level, the curves do not differ substantially from the ones observed for ACN, with a polarization-versus-concentration trend similar to the one observed in the top panel. Note that results for the limiting  $x_{\text{ACN}} = 0$  case agree to results reported in Ref. [44,50], indicating that the O=S bond remains parallel to the surface.

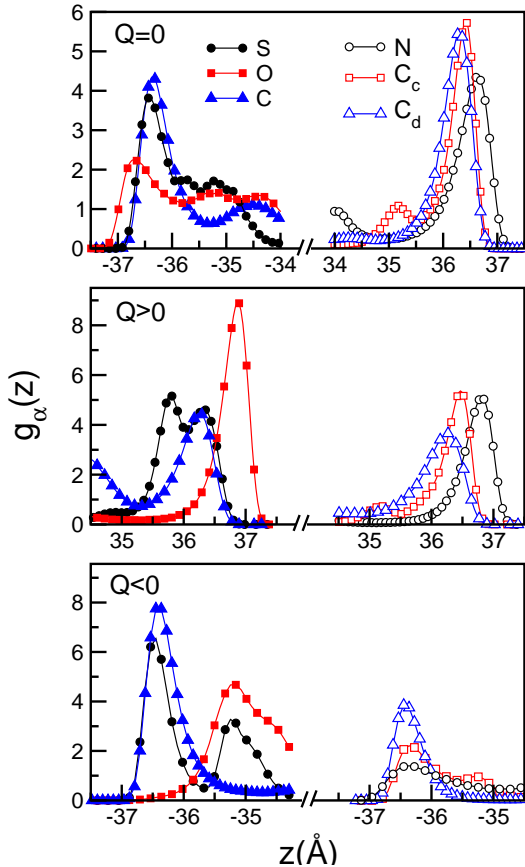

Figure 4: Local site densities of ACN (open symbols) and DMSO (filled symbols) for an  $x_{\text{ACN}} = 0.5$  mixtures in the vicinity of different liquid/graphene interfaces. Top panel: uncharged plate; middle panel: positively charged plate; bottom panel: negatively charged plate. Filled(open) symbols correspond to DMSO(ACN) molecules.  $C_d$  and  $C_c$  denote distal and central atoms in the ACN molecule, respectively (see text).

## Liquid/graphene interfaces

We will now move to the analysis of liquid/graphene interfaces, examining local site densities in the vicinity of uncharged plates which are depicted in the top panel of Fig. 4. The plots correspond distribution functions similar to the ones described in Eq.1, for the  $z$ -components of different site coordinates. For the sake of concision, we will restrict our analysis to the  $x_{\text{ACN}} = 0.5$  case as a representative mixture, unless necessary to illustrate distinctive features. The plots present highly irregular characteristics that extend for about  $\sim 10 - 15$  Å inwards from the plates before level off at unity. To facilitate the description, it will be instructive to simultaneously analyze the results of the distribution of local polarizations that appear in the bottom panel of Fig. 3 ( $Q = 0$ ). In this case, the sampling was restricted to those molecules with at least one site lying under the main peaks of  $g(z)$ , i.e. those satisfying  $|z_{\alpha}^i| > 35.5$  Å. For ACN, the polarization distribution (blue squares) exhibits a broad main peak at  $\cos\theta \sim -0.15$  and a much milder feature at  $\cos\theta \sim 1$ . As such, molecular configurations in which the ACN axis lies practically parallel to the solid surface prevail, along with a smaller probability of arrangements in which only the positively charged, distal  $\text{CH}_3$  with dangling H, remains in contact with the solid substrate. The set of curves in Fig. 4 confirms this geometrical arrangement: Note that the main peaks for the three axial sites lie within a  $\sim 0.5$  Å wide interval, centered at  $\sim 36.4$  Å, and exhibiting comparable areas; in addition, one can also perceive secondary peaks  $\sim 1.3$  Å (C-central) and  $\sim 2.4$  Å (N) inwards into liquid phase; these lengths are comparable to the intramolecular distances between the C-distal and the latter sites, indicating molecular orientations mostly perpendicular to the graphene sheet. The  $g(z)$  profiles for DMSO look more irregular, which is somehow expected given the larger variety of intramolecular lengthscales controlling the resulting molecular packing at the graphene walls. The interpretation of the dipolar distribution (red squares) with a bimodal character looks much more straightforward, suggesting that configurations with the  $\text{CH}_3$  groups and O-sites in contact with the plates are equally likely to be observed.

Local concentrations of the two species at the graphene walls are listed in column 3 of

Table 1.b and are also depicted in Fig. 2 (open circles). Contrasting with the liquid/air interfaces, the observed propensity is reversed and the local concentrations of ACN at the walls are smaller than those prevailing in the bulk phases. In addition, the magnitudes of these modifications look less marked, compared to the ones reported for liquid/air interfaces. We further exploited the simplicity of the different hypothesis leading to Eq. 2 to analyze this qualitative modification in the trends. Eq. 2 requires estimates for the difference between liquid/solid surface tensions,  $\gamma_{ACN}^{ls} - \gamma_{DMSO}^{ls}$  which, in turn, can be obtained via the classical Young expression, namely:

$$\gamma_{ACN}^{ls} - \gamma_{DMSO}^{ls} = \gamma_{DMSO}^{lv} \cos \theta_{DMSO}^Y - \gamma_{ACN}^{lv} \cos \theta_{ACN}^Y \quad ; \quad (7)$$

where  $\theta_{\alpha}^Y$  represent the contact angle at the liquid/gas/solid intersection. Unfortunately, we failed to find direct experimental data for these angles; as an alternative, we resorted to the correlation reported by Shen et al.<sup>51</sup> between  $\cos \theta_{\alpha}^Y$  and the so-called “dispersive” and “polar” components<sup>52,53</sup> of  $\gamma_{\alpha}^{lv}$  for a series solvents, including DMSO and ACN.<sup>54</sup> Results from Eqs. 2 and 7, with  $\cos \theta_{\alpha}^Y$  set at 0.70(DMSO) and 0.92(ACN) and  $\bar{A} = 24 \text{ \AA}^2$ , appear in Fig. 2 (dot-dashed lines).<sup>54</sup> Similarly to what we registered for the liquid/vapor interfaces, Eq. 2 appears equally successful in capturing the basic ingredients controlling concentration fluctuations in the vicinity of the graphene walls as well. In passing, we remark the reported disparity<sup>51</sup> between the “dispersive/polar” ratios for the ACN= 0.45 and for DMSO= 4.5 which, in turn, would suggest that the inversion in the surface propensity could be ascribed mostly to a stronger nature of the surface unbalances in the dispersive DMSO-graphene interactions.

Compared with the previous  $Q = 0$  cases, the incorporation of additional Coulomb coupling between the plates and the liquid mixtures promotes more marked deviations in the local densities from the bulk ones, (see colored circles in Fig. 3) For example, for the  $x_{ACN} = 0.5$  mixture, the ACN-depletions at charged interfaces fall down to  $x_{ACN}^{srf} = 0.38 \pm 0.03$

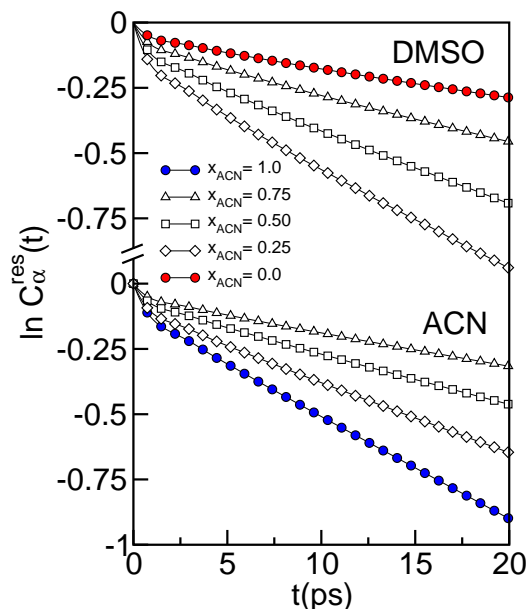

Figure 5: Population relaxation of DMSO (top curves) and ACN (bottom curves) molecules lying at liquid-mixture/air interfaces. Also shown are results for pure liquid phases (colored circles).

for the  $Q > 0$  plate(cathode) and  $x_{\text{ACN}}^{\text{sr}f} = 0.29 \pm 0.03$  for the  $Q < 0$  plate(anode). Note that these asymmetries in the solvation at the walls could not be anticipated based on the sole consideration of the magnitudes of the corresponding dipolar moments, which for ACN and DMSO are of similar magnitude. This reinforces the idea that the prevailing local structures are the result of complex interplays between packing effects and Coulomb couplings of difficult prediction. Still, as expected, the plots for  $g(z)$  at the anode (middle panel of Fig. 4) are dominated by main peaks for negatively charged sites, located at  $z \sim 37 \text{ \AA}$ , whereas the mirrored scenario appears at the cathode, where the main peak at  $z \sim -36.5 \text{ \AA}$  now corresponds to the methyl carbons (bottom panel). Polarization distributions shown in the bottom panel of Fig. 3 ( $Q \neq 0$ ) exhibit shifts towards negative values of  $\cos \theta$  (somewhat more marked for the DMSO molecules); this observation is accordant with the presence of a net polarization, parallel to the external electric field spanning the fluid phase.

# Dynamical Characteristics

We will begin our dynamical analysis by focusing on the characteristics of translational and rotational motions of the two components at the different interfaces. One should keep in mind that the presence of the different interfaces brings the different dynamical modes anisotropic. Exploiting the cylindrical symmetry of the systems, parallel and perpendicular diffusion coefficients are normally computed from restricted samplings of mean-square displacements in the vicinity of interfaces<sup>55-58</sup> or from a more complex computation of the diffusion tensor at the interfaces.<sup>59</sup> Information about the perpendicular diffusive characteristics of interfacial molecules can be extracted from the values of  $\tau^{res}$ , the average residence times. As such, one should reasonably expect that larger diffusion constants along the latter axis should go hand-in-hand with shorter residence times and vice versa.

The usual route to estimate  $\tau_{res}$  involves the computation of time correlation functions of the type:

$$C_{\alpha}^{res}(t) = \frac{\langle \eta_{\alpha}^i(t) \cdot \eta_{\alpha}^i(0) \rangle}{\langle [\eta_{\alpha}^i(0)]^2 \rangle} \quad ; \quad (8)$$

where the function  $\eta_{\alpha}^i(t)$  equals 1 if the tagged  $i$ -th molecule of species  $\alpha$  lies continuously at the surface within a  $[0,t]$  interval, except during brief time spans of length  $\tau$ , and zero otherwise. The consideration of values of  $\tau$  different from zero relaxes the definition of surface residence by disregarding eventual fast recrossings of the bulk/surface boundaries occurring on timescales much smaller than the resulting  $\tau^{res}$ . Following previous studies,<sup>23</sup> we set  $\tau = 2$  ps.

Results for  $\ln C_{\alpha}^{res}(t)$  for liquid-mixture/air interfaces are depicted in Fig. 5. After initial,  $\sim 2$  ps, time intervals all curves can be reasonably approximated by single exponentials. Estimates for  $\tau^{res}$  obtained from linear fittings of the decays for  $t > 5$  ps appear in columns 2 and 3 of Table 2. Incidentally, we would like to remark that the reported value of  $\tau_{DMSO}^{res}$  for pure DMSO exceeds the one reported in Ref. [44] by a factor of  $\sim 2.5$ ; we attribute this discrepancy to a deficiency of the  $FS$  Hamiltonian for DMSO, which also underestimates the

diffusion constant in the bulk.<sup>31</sup> Coming back to the results listed in Table 2, two features are worth remarking: (i) residence times for both species present steady increments as the molar fraction of ACN diminishes and (ii) at fixed concentrations, the values of  $\tau_{\text{ACN}}^{\text{res}}$  look longer than the corresponding  $\tau_{\text{DMSO}}^{\text{res}}$ . Note that, while the former trend (i) is also observed in the bulk, the latter (ii) is just the opposite one, since diffusion constants for ACN in bulk mixtures are larger than those reported for DMSO.<sup>11</sup> The latter feature, in turn, would corroborate the more marked stabilization of ACN at the interfaces. Similar arguments have been raised to rationalize longer residence times of methanol and acetone in aqueous mixtures,<sup>22,60</sup> although in the latter cases, the reasons for the stabilizations were rationalized in terms of the hydrophobic-like characteristics of liquid/vapor interfaces.<sup>24-26</sup>

One can further explore the physical grounds underlying the latter feature by combining our previous surface/bulk equilibrium description of the slab along with the classical model by Zwanzig,<sup>61</sup> that portrays diffusion in the bulk as a sequence of uncorrelated activated jumps, involving passages over free energy barriers of magnitude  $\Delta F^{\ddagger}$ . Let us now focus on the transfer of a tagged molecule of species  $\alpha$  from the surface into the bulk. Assuming that the activation barrier picture still holds for this process, surface-to-bulk transfers should involve surmounting a lower free energy barrier of magnitude  $\Delta F_{\alpha}^{\ddagger} - \gamma_{\alpha} \bar{A}$ . Consequently, a simple transition state theory treatment leads to the following expression for the ratio

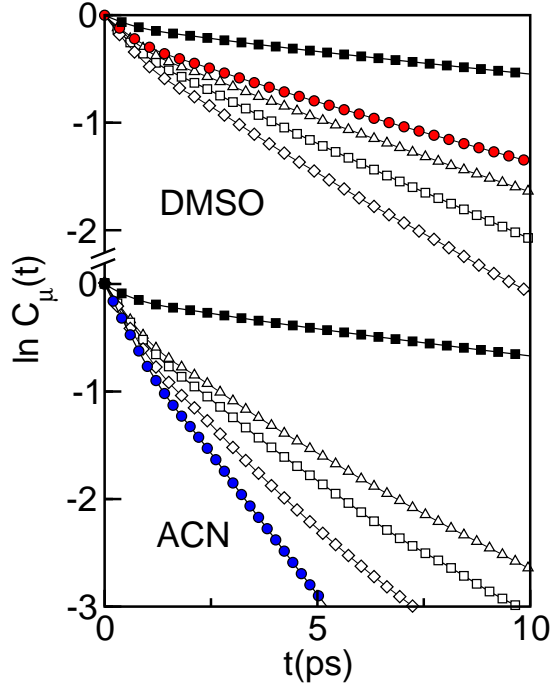

Figure 6: Orientational relaxations of DMSO (top curves) and ACN (bottom curves) molecules lying at liquid-mixture/air interfaces. Same labeling as in Fig. 5. Results shown with black squares correspond to an  $x_{\text{ACN}} = 0.5$  mixture at the liquid-mixture/graphene ( $Q = 0$ ) interface.

between the residence times of the two components:

$$\frac{\tau_{\text{ACN}}^{\text{res}}}{\tau_{\text{DMSO}}^{\text{res}}} \sim \exp(-\beta\Delta F) \quad (9)$$

with

$$\Delta F = \Delta F_{\text{DMSO}}^{\dagger} - \Delta F_{\text{ACN}}^{\dagger} + (\gamma_{\text{ACN}}^{lv} - \gamma_{\text{DMSO}}^{lv}) \bar{A} \quad ; \quad (10)$$

where we have disregarded eventual differences in the temporal prefactors that relate the exchange rates for the two species with the corresponding Boltzmann factors. By replacing estimates for  $\Delta F_{\text{DMSO}}^{\dagger} = 12 \text{ kJ mol}^{-1}$  and  $\Delta F_{\text{ACN}}^{\dagger} = 11 \text{ kJ mol}^{-1}$  reported in Refs. [62] and [63] and the aforementioned values of the surface tensions in Eqs. 9 and 10, our approximated approach yields  $\tau_{\text{ACN}}^{\text{res}}/\tau_{\text{DMSO}}^{\text{res}} = 1.4$ , a value that compares favorably well with the ratios obtained from the entries of Table 2, which are intermediate between 1.38 and 1.46. The

previous “back-of-the-envelope” calculation involves several approximations requiring further validations; in particular, the one assuming that the magnitudes of the diffusion free energy barriers in the isotropic pure liquids environments can be directly transferred to estimate those modulating jumps along perpendicular directions in liquid-mixtures/vapor interfaces. Anyhow, the quality of the agreement might indicate that the previous hypothesis is valid or the eventual differences cancel out in the subtraction that appears in the second term of Eq. 10. As such, our results would indicate that Zwanzig’s activation-energy picture provides a simple explanation for the differences observed in the residence times. We finally stress that our attempts to obtain meaningful information for the exchange dynamics of molecules at liquid/graphene interfaces turned out unsuccessful. At these environments, we found that  $\tau_{\alpha}^{res}$  values stretch into the ns time domain, bringing the lengths of our simulations runs insufficient to harvest appropriate statistics.

The characteristics of the orientational mobilities at the interfaces were analyzed by computing individual dipole-dipole time correlation functions of the type:

$$C_{\mu}^{\alpha}(t) = \frac{\langle \delta \boldsymbol{\mu}_i^{\alpha}(t) \cdot \delta \boldsymbol{\mu}_i^{\alpha}(0) \rangle_{surf}}{\langle |\delta \boldsymbol{\mu}_i^{\alpha}|^2 \rangle_{surf}} \quad . \quad (11)$$

where  $\delta \boldsymbol{\mu}_i^{\alpha}(t) = \boldsymbol{\mu}_i^{\alpha}(t) - \langle \boldsymbol{\mu}_i^{\alpha} \rangle_{surf}$ . Plots for  $\ln C_{\mu}^{\alpha}$  for liquid/air interfaces are displayed in Fig. 6, whereas characteristic timescales for rotational motions,  $\tau_{\alpha}^{\mu}$ , appear in columns 4 and 5 of Table 2. The latter values correspond to linear fits of the plots for  $t > 3$  ps. The simultaneous inspection of the curves in Fig. 6 and the entries in Table 2 reveal gradual retardations in the dynamics of both components as the concentration of ACN diminishes. This concentration trend is in agreement with the one registered for residence timescales. In this context, it is also interesting to compare values of  $\tau_{\alpha}^{\mu}$  to those observed *in the bulk*, also listed between parentheses in the aforementioned Table. In all cases, the looser structure at the surface due to the reduction in the intermolecular connectivity leads to faster decorrelations in the orientational dynamics, with characteristic times which are approximately one half of those

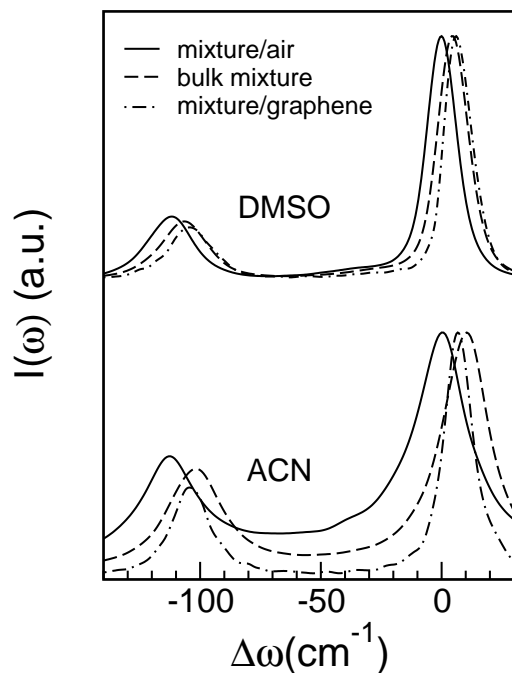

Figure 7: Infrared bands corresponding to C-H symmetric (low frequencies) and asymmetric (high frequencies) stretching modes for ACN/DMSO mixtures at different environments. The frequency shifts are expressed relative to the position of the asymmetric band in mixture/air interfaces. To facilitate the comparison, the heights of the asymmetric bands were brought to a same value.

registered in the bulk. The entries listed in the last two columns at the right hand side of Table 2, reveal that orientational timescales at the walls are practically one order of magnitude longer than those reported for liquid-mixture/air interfaces.

We will close this section by briefly commenting on the characteristics of spectral shifts in the infrared spectra of the two components at these interfaces. Signals from localized vibrations along the C-H bonds obtained from surface-selective techniques are known to be adequate to gauge the modifications operated in concentrations and intermolecular connectivities at liquid/vapor interfaces.<sup>14,17,50,64</sup> Within the simplest classical approach, information about IR C-H bands can be obtained from Fourier transforms of velocity time correlation

functions of interfacial H-sites, namely:

$$I(\omega) \propto \int_{-\infty}^{\infty} C_{vv}(t) \cos \omega t dt \quad ; \quad (12)$$

where

$$C_{vv}(t) = \langle \mathbf{v}_i^H(0) \cdot \mathbf{v}_i^H(t) \rangle_{srf} \quad . \quad (13)$$

In Fig. 7 we present results for  $I(\omega)$  for the representative,  $x_{ACN} = 0.5$  mixture. In the abscissa axis, frequency shifts  $\Delta\omega$  are expressed relative to the positions of the centers of the corresponding asymmetric stretch bands for liquid/air interfaces. In passing, we remark that we made no efforts to modify the parametrization of our intramolecular Hamiltonians, to bring the positions of the different bands in agreement with experimental information. As such, our force field predicts C-H peaks that fall, typically,  $\sim 100 \text{ cm}^{-1}$  blue-shifted. All plots shown in Fig. 7 present two bands, which we assign to symmetric (low frequencies) and asymmetric (high frequencies) C-H modes. Moreover, the signals for the bulk (dashed lines) appear  $\sim 10 \text{ cm}^{-1}$  blue-shifted, with respect to the liquid/air interfaces (solid lines). This trend has been previously reported by Allen et al.,<sup>14,17</sup> who performed vibrational sum frequency spectroscopic experiments liquid/air interfaces involving water/DMSO mixtures. Note that this peculiar behavior is at odds with the one observed in interfaces involving strong hydrogen-bonded substances, like water/vapor ones, in which the presence of dangling hydrogens shift surface frequencies toward higher frequencies, compared to the bulk ones. Contrasting, here, the intermolecular connectivity involving  $\text{CH}_3$  groups would be compatible with what is usually referred to as X-H $\cdots$ Y, “improper hydrogen bonds”. The latter terminology that has been coined to denote coordination-induced, X-H bond contractions.<sup>65,66</sup> In fact, results from quantum calculations indicate that the resulting modifications of the X–H distances are the result of charge transfer processes controlled by a competition between, on the one hand, the electron affinity of the donor-atom X and, on the other, the attractive interaction between the positively charged H and the acceptor-atom Y. Surprisingly

enough, despite the simplicity of the our classical force field, our simulation result predict not only the observed blue-shift trend in the bulk but also the correct order of magnitude, i.e.  $\sim 10\text{-}20$  wavenumbers. We remark that we found no relevant modifications in the C-H bond-lengths between bulk and surface molecules to corroborate this way of reasoning. However, this should not be totally unexpected, considering that electronic structure calculations show that modifications in the X-Y distance of the order of  $10^{-2}$  Å are enough to explain the frequency shifts. Finally, note that, as a result of additional wall-CH<sub>3</sub> interactions, the signals corresponding to liquid/graphene interfaces practically coincide with the bulk ones.

## Concluding Remarks

We have presented a detailed analysis that included structural characteristics and key-dynamical properties of aprotic mixtures combining ACN and DMSO, at different interfaces. At liquid/vapor ones, our simulations reveal a clear preference of ACN to lie adjacent to the vapor phase. For example, for  $x_{\text{ACN}} = 0.25$  mixtures, deviations in the local concentrations from the bulk-mixture values are reflected in practically  $\sim 70\%$  increments in the ACN surface density. By considering a simple model in which interfacial and bulk environments are pictured as two phases in equilibrium, we succeeded in describing the extent of this tendency remarkably well. Moreover, the implemented model clearly indicates that the sole consideration of the difference between the air/liquid surface tensions of the pure liquids would be enough to reproduce the simulation results.

The analysis of orientational correlations was evaluated in terms of distributions of the individual dipolar alignments with respect to the direction normal to the liquid/vapor interfaces. Starting from ACN-rich solutions, we observed a mild tendency towards orientations in which the dipoles point out, into the gas phase; contrasting, in DMSO-rich scenarios, the preferential orientations look mostly parallel to the interface. The incorporation of wall/solvent dispersive forces that prevail close to hydrophobic-like solid plates leads to stronger restric-

tions in orientational fluctuations of the adjacent liquid phases. For equimolar mixtures, the vast majority of the ACN molecules present dipolar alignments parallel to the plates, along with a much minor fraction, that expose the distal methyl group to the solid phase. The complex interplay between the variety of distances describing the geometry of DMSO molecules along with those describing the individual site-wall interactions precluded a clear interpretation of the local solvation structure of the latter component. Still, the dipolar distribution for DMSO presents a much more simple bimodal character, suggesting local arrangements, with equally-likely parallel and antiparallel alignments.

Contrasting with the liquid/vapor interface description, the previously reported ACN surface propensity reverses at hydrophobic walls, giving rise to somewhat less marked, albeit clear, enhancements of DMSO concentrations. Interestingly, a similar equilibrium analysis, expressed now in terms of differences in the corresponding solid/liquid surface tensions was also found to be adequate to explain the inversion in the competition for interfacial positions. The incorporation of Coulomb coupling between the graphene walls and the liquid phase, in turn, reinforced the DMSO propensity most notably, close to the cathode wall. As expected, this additional coupling modified the orientational distributions towards profiles which were accordant with the presence of a net polarization across the fluid phase, parallel to the external electric field. The preferential solvation of DMSO at charged plates observed here would agree with magnitudes of the signals of interfacial infrared spectroscopy measurements reported in Ref. [67].

The concentration dependence of the overall dynamics of the mixtures at the interfaces followed trends similar to the ones observed in the bulk. As such, the characteristic time scales describing the different dynamical modes stretched, as the concentration of ACN diminished. As a singularity, at fixed concentrations, we detected ACN residence times at liquid/vapor interfaces longer than those observed for DMSO molecules, despite the fact that, in the bulk, ACN molecules diffuse faster than DMSO ones. By combining the bulk-interface equilibrium description with the activated picture of diffusion proposed by Zwanzig,

we succeeded in interpreting the latter differences invoking classical transition state theory arguments. Still, the transferability of estimates for free energy barriers controlling isotropic diffusive motions in the bulk to those modulating anisotropic modes at interfaces deserves further investigations which are well beyond the scope of this work.

Finally, we performed a classical analysis to detect spectral shifts in the IR spectra of surface molecules, by focusing on the corresponding C-H stretching bands. Despite the simplicity of our Hamiltonian, we found spectral shifts that agree at a qualitative level with those reported from surface-sensitive spectroscopic techniques. These modifications are compatible with the presence of “blue-shifted” hydrogen bonds, contrasting sharply with the red shifts otherwise recorded in interfacial scenarios hosting strongly hydrogen-bonded substances.

Summarizing, the simulation results presented in this paper shed light on a variety of new behaviors that complement previous studies dealing with mixtures combining, for example, protic/aprotic components at different interfaces. Our description is far from complete and further analyses will be necessary to bring additional support to several of the approximations underlying the main conclusions drawn from this study. Yet, our physical interpretations, based on fundamental physicochemical arguments, would confirm that our approach retains the key ingredients controlling the structure and the dynamical behavior of aprotic mixtures at liquid/air and liquid/graphene interfaces.
