A General Method for the Numerical Computation of Manipulator Singularity Sets

Oriol Bohigas, Dimiter Zlatanov, Lluís Ros, Montserrat Manubens, Josep M. Porta

Abstract—The analysis of singularities is central to the development and control of a manipulator. However, existing methods for singularity set computation still concentrate on specific classes of manipulators. The absence of general methods able to perform such computation on a large class of manipulators is problematic, because it hinders the analysis of unconventional manipulators and the development of new robot topologies. The purpose of this paper is to provide such a method for non-redundant mechanisms with algebraic lower pairs and designated input and output speeds. We formulate systems of equations describing the whole singularity set and each one of the singularity types independently, and show how to compute the configurations in each type using a numerical technique based on linear relaxations. The method can be used to analyze manipulators with arbitrary geometry and it isolates the singularities with the desired accuracy. We formulate the specification of the conditions and their numerical solution with examples, and use three-dimensional projections to visualize the complex partitions of the configuration space induced by the singularities.

Index Terms—Singularity set computation, non-redundant manipulator, linear relaxation, branch-and-prune method.

I. INTRODUCTION

In robot singularities either the forward or the inverse instantaneous kinematic problem becomes indeterminate, and the properties of the mechanism change dramatically, often detrimentally. Despite the importance of such critical configurations, the rich literature on singularity analysis does not provide a method to explicitly compute the singularity set, and to identify the various singularity types in it, on manipulators of a general architecture. Most works on the topic focus on particular classes of singularities, and restrict their attention to specific robot designs [1]–[13].

The efforts on characterizing all possible singularity types date back to the nineties [14]–[19]. Based on an input-output velocity equation, a general singularity classification was attempted in [14], but it was soon seen that this classification overlooks cases where the motion of the mechanism cannot be described solely with the input and output speeds [15]. This led Zlatanov to define a general manipulator model in terms of differentiable mappings between manifolds, giving rise to a rigorous mathematical definition of kinematic singularity [16, 18]. Using the model, six different singularity types were identified, corresponding to the distinct kinematic phenomena that may occur in a singularity.

Although the conditions for the presence of singularities of all types were given in [17, 18], the formulation of these conditions into a form amenable for computation had not been achieved yet. The goal of the present work is to address this task by defining systems of equations describing all singularity types, and proposing a numerical procedure able to solve them. The methodology is general and applicable to virtually any relevant mechanism geometry. It allows the complete singularity set to be obtained with the desired accuracy, and each of its singularity types to be computed independently.

The approach was preliminarily introduced in [20] and is now presented and illustrated in thorough detail. The guiding principle is the importance of a complete characterization of the manipulator motion in order to identify all possible singular phenomena. For each such phenomenon we present, simply and rigorously, the definition, the mechanical significance, the algebraic conditions, and the computation of the corresponding singularity subset. Special emphasis is placed on illustrating concepts and procedures with clear and comprehensible examples. Also, since a full knowledge of a mechanism’s special configurations is key to understanding its motion capabilities, the paper exemplifies the use of three-dimensional projections to reveal and visualize the complex singularity-induced partition and interconnectedness of the configuration space.

The rest of the paper is organized as follows. Section II briefly recalls the definition of singular configuration, and provides systems of equations characterizing the whole singularity set of a manipulator. These systems can already be used to isolate the set, as done in [21] for the planar case, but additional systems are provided in Section III to independently compute the configurations belonging to each one of the six singularity types identified in [16, 18]. The derivation and application of these systems is next illustrated in Section IV on a simple example admitting an analytical approach. In general, a numerical method is needed to solve the equations, and Section V provides one based on a branch-and-prune strategy and linear relaxations. Section VI demonstrates the performance of the method with the analysis of a planar and a spatial manipulator. Finally, Section VII summarizes the main conclusions of the paper, and suggests points for future work.
II. CHARACTERIZATION OF THE SINGULARITY SET

Every configuration of a manipulator can be described by a tuple $q$ of scalar generalized-coordinate variables. For manipulators with closed kinematic chains, or when a joint does not admit a global parametrization, the configuration space is given by the solution set of a system of non-linear equations

$$\Phi(q) = 0,$$

which expresses the assembly constraints imposed by the joints [22]. In addition, the feasible instantaneous motions of the manipulator can be characterized by a linear system of equations

$$Lm = 0,$$

where $L$ is a matrix that depends on the configuration $q$, and $m$ is the so-called velocity vector of the manipulator [18]. The vector $m$ takes the form $m = [\Omega^p, \Omega^o, \Omega^r]^T$, where $\Omega^r$, $\Omega^o$, and $\Omega^p$ provide the output, input, and passive velocity vectors, respectively. Typically, $\Omega^r$ encodes the velocity of a point and/or the angular velocity of an end-effector body, and $\Omega^o$ and $\Omega^p$ encompass the actuated and unactuated joint speeds. Such a system, called the velocity equation in [18], can be obtained for any manipulator [23], and therefore it can be used for the practical identification of singularities.

In this paper we assume that the manipulator is non-redundant. This implies that the dimensions of $\Omega^o$ and $\Omega^a$ are equal to the global mobility $n$ of the mechanism, defined as the dimension of the configuration space, i.e., as the maximum dimension of its tangent space, wherever such a space exists [24].

In general, the instantaneous kinematic analysis of a manipulator addresses two main problems:

- The forward instantaneous kinematics problem (FIKP): find $m$ given the input velocity $\Omega^p$.
- The inverse instantaneous kinematics problem (IIKP): find $m$ given the output velocity $\Omega^o$.

Note that, contrary to what is assumed elsewhere [14], in both cases it is required to find all velocity components of $m$, not just those referring to the output or input velocities, respectively. Following [18], a configuration is said to be nonsingular when both the FIKP and the IIKP have unique solutions for any input or output velocity, and singular otherwise.

Let $L_I$, $L_O$, and $L_P$ be the submatrices of $L$ obtained by removing the columns corresponding to the input, output, and both the input and output velocities, respectively. It is easy to see that the singular configurations are those in which either $L_I$ or $L_O$ is rank deficient. If a matrix is rank deficient, its kernel has to be non-null and, in particular, it must include a vector of unit norm. Thus, all singularities can be determined by solving the following two systems of equations:

$$\Phi(q) = 0, \quad L_I^\dagger\xi = 0, \quad \|\xi\|^2 = 1, \quad L_O^\dagger\xi = 0, \quad \|\xi\|^2 = 1.$$  \hspace{1cm} (3)

The first equation of each system constrains $q$ to be a feasible configuration of the mechanism, and the second and third equations enforce the existence of a nonzero vector in the kernel of the corresponding matrix. Note that $\|\xi\|^2$ can be any consistent norm, for instance $\xi^TD\xi$, with $D$ a diagonal matrix with the proper physical units. There is no need for the norm to be invariant with respect to change of frame or units. In short, the condition $\|\xi\|^2 = 1$ only serves to guarantee that $\xi$ is not 0. The solutions of the system on the left in Eq. (3) include all singularities where the FIKP is indeterminate (forward singularities), while the solutions of the system on the right include all singularities where the IIKP is indeterminate (inverse singularities).

Now, depending on the cause of the degeneracy, six substantially different types of singularities can be recognized. These are redundant input (RI), redundant output (RO), impossible input (II), impossible output (IO), increased instantaneous mobility (IM), and redundant passive motion (RPM) singularities. Each of the six types corresponds to a different change in the kinematic properties of the manipulator, and it is therefore desirable to know whether a configuration belongs to a given type, and to compute all possible configurations of that type.

III. CHARACTERIZATION OF THE SINGULARITY TYPES

The definitions of each one of the six singularity types are recalled next. Following each definition, a system of equations characterizing the configurations of the type is derived. The 3-slider and 4-bar mechanisms of Fig. 1 are used to illustrate the different singularity types on mechanisms with prismatic and revolute joints. Each mechanism has one degree of freedom and, unless otherwise stated, the input and output velocities are those of points $A$ and $B$, $v_A$ and $v_B$, for the 3-slider mechanism, and the angular velocities of links $AB$ and $DC$, $\omega_A$ and $\omega_D$, for the 4-bar mechanism.

Redundant Input

A configuration is a singularity of RI type if there exist an input velocity vector $\Omega^p \neq 0$, and a vector $\Omega^a$, that satisfy the velocity equation (2) for $\Omega^o = 0$, i.e., such that

$$L_O \begin{bmatrix} \Omega^a \\ \Omega^p \end{bmatrix} = 0,$$
A configuration is a singularity of IO type if there exists a vector $\Omega^o \neq 0$ in the output-velocity space for which the velocity equation cannot be satisfied for any combination of $\Omega^o$ and $\Omega^o$. This means that there is a nonzero vector $[\Omega^o,0^T,0^T]^T$ that cannot be obtained by projection of any vector $[\Omega^o^T,\Omega^o^T,0^T]^T$ belonging to the kernel of $L$.

In order to derive the system of equations for this type, let $V = [v_1, \ldots, v_r]$ be a matrix whose columns form a basis of the kernel of $L$. Then, all vectors $[\Omega^o^T,0^T,0^T]^T$ that can be obtained by projection of some vector of the kernel of $L$ are those in the image space of the linear map given by

$$A = \begin{bmatrix} I_{n \times n} & 0 \end{bmatrix} V,$$

where $n$ is the dimension of $\Omega^o$. Thus, a singular configuration is of IO type if the map is not surjective, i.e., if $A$ is rank deficient. In this situation it can be seen that there exists a unit vector $\Omega^o^*$ in the kernel of $A^T$ and, hence, a vector $[\Omega^o^*,0^T,0^T]^T$ in the kernel of $V^T$. Such a vector is orthogonal to all vectors $v_1, \ldots, v_r$, so it must belong to the image of $L^T$. In conclusion, there must exist a nonzero vector $\Omega^o^*$ satisfying

$$L^T u = \begin{bmatrix} \Omega^o^* \\ 0 \\ 0 \end{bmatrix},$$

for some vector $u$, which can be chosen of unit norm. Therefore a configuration $q$ is an IO type singularity if, and only if, it satisfies

$$L^T u = \begin{bmatrix} \Phi(q) = 0 \\ \Omega^o^* \\ 0^T \\ 0^T \end{bmatrix},$$

with $\Omega^o^* \neq 0$. For all solutions of this system, the obtained value of $\Omega^o^*$ corresponds to a non-feasible output at the corresponding configuration.

### Impossible Output

The six singularity types exemplified with 3-slider and 4-bar mechanism configurations.

#### Table I

<td><img src="IIM.png" alt="Diagram" /></td>
</tr>
</tbody>
</table>

- $L_1 < L_2$
- $L_1 > L_2$
- $L_1 = L_2$

with $\Omega^o \neq 0$. Since such a vector exists whenever there exists a unit vector with $\Omega^o \neq 0$, $q$ is a singularity of RI type if, and only if, the system of equations

$$\begin{cases} \Phi(q) = 0 \\ L_1 \xi = 0 \\ \|\xi\|^2 = 1 \end{cases}$$

is satisfied for some value of $\xi = [\Omega^o^T,\Omega^o^T]^T$ with $\Omega^o \neq 0$.

Two examples of these singularities are provided in Table I, first column. In the top configuration, $v_A$ can have any value, while $v_C$ must be zero and, thus, point $B$ cannot move. In the bottom configuration the output link $DC$ cannot move, since the velocity of point $C$ must be zero, while $\omega_A$, can have any value.

#### Redundant Output

A configuration is a singularity of RO type if there exist an output velocity vector $\Omega^o \neq 0$, and a vector $\Omega^o$, that satisfy the velocity equation for $\Omega^o = 0$, i.e., such that

$$L_1 \begin{bmatrix} \Omega^o^* \\ \Omega^o \end{bmatrix} = 0,$$

with $\Omega^o \neq 0$. Following a similar reasoning as above, $q$ is of RO type if, and only if, it satisfies the equations

$$\begin{cases} \Phi(q) = 0 \\ L_1 \xi = 0 \\ \|\xi\|^2 = 1 \end{cases},$$

for some value of $\xi = [\Omega^o^*,\Omega^o^T]^T$ with $\Omega^o \neq 0$.

The 3-slider and the 4-bar mechanisms in the second column of Table I are shown in a singularity of RO type. On the former, the instantaneous output $v_B$ can have any value while point $A$ must have zero velocity. The same happens on the latter, where the input link $AB$ is locked while the instantaneous output, $\omega_D$, can have any value.
The configurations in the first column of Table I are also singularities of IO type because any nonzero output is impossible in them.

**Impossible Input**

A configuration is a singularity of II type if there exists an input velocity vector $\Omega^p \neq 0$ for which the velocity equation cannot be satisfied for any combination of $\Omega^a$ and $\Omega^p$. Following a similar reasoning as for the IO type, a configuration $q$ is a singularity of II type if, and only if, there exists a nonzero vector $\Omega^a$ such that

$$L^T u = \begin{bmatrix} 0 \\ \Omega^a \\ 0 \end{bmatrix},$$

for some vector $u$, which can also be chosen of unit norm. Thus, a configuration $q$ will be a singularity of II type if, and only if, it satisfies

$$L^T u = \begin{bmatrix} \Phi(q) = 0 \\ 0^T \Omega^a + 0^T \\ \|u\|^2 = 1 \end{bmatrix},$$

(7)

with $\Omega^a \neq 0$.

The 3-slider and the 4-bar mechanisms in the second column of Table I are also in singularities of II type since any nonzero input is impossible in these configurations.

**Redundant Passive Motion**

A configuration is a singularity of RPM type if there exists a vector $\Omega^p$ in the input-velocity space that satisfies the velocity equation for $\Omega^a = 0$ and $\Omega^p = 0$, i.e., such that

$$L_P \Omega^p = 0,$$

with $\Omega^p \neq 0$. This will happen when the kernel of $L_P$ is nonzero and, thus, the following system of equations

$$\begin{aligned}
\Phi(q) &= 0 \\
L_P \Omega^p &= 0 \\
\|\Omega^p\|^2 &= 1
\end{aligned}$$

(8)

encodes all RPM type singularities $q$.

Two examples of these singularities are provided in Table I, third column. In the 3-slider mechanism, both the input $A$ and the output $B$ must have zero velocity, while the velocity of point $C$ can be nonzero. A 4-bar mechanism with a kite geometry, as shown in the table, can collapse so all joints lie on a single line and $B$ and $D$ coincide. If the input and output are the velocities at joints $A$ and $C$, $\omega_A$ and $\omega_C$, the mechanism can move from the configuration shown in gray, maintaining zero-velocity at both the input and output joints. Nonzero velocity is present only at the passive joints $B$ and $D$. Hence, both mechanisms are shown in a singularity of RPM type.

**Increased Instantaneous Mobility**

A configuration is a singularity of IIM type if $L$ is rank deficient. In fact, these are configurations where the instantaneous mobility is greater than the number of degrees of freedom. The definition directly allows to write the system of equations

$$\begin{aligned}
\Phi(q) &= 0 \\
L^T \xi &= 0 \\
\|\xi\|^2 &= 1
\end{aligned}$$

(9)

which will be satisfied for some $\xi$ by a configuration $q$ if, and only if, it is a singularity of IIM type. These are also called configuration-space singularities, because they correspond to points where the tangent space is ill-defined, and thus, both the FIKP and IIKP become indeterminate for any definition of input or output on the given velocity variables.

The mobility of the 3-slider and the 4-bar mechanisms in the fourth column of Table I increases from 1 to 2 at the shown configurations and, thus, they exhibit a singularity of IIM type.

**IV. AN ILLUSTRATIVE EXAMPLE**

To exemplify how the previous systems can be used to obtain the configurations of each singularity type, consider the 3-slider mechanism in Fig. 1. Let $(x_P,y_P)$ denote the coordinates of points $P \in \{A,B,C\}$ relative to the reference frame $OXY$ in the figure, and let $L_1$ and $L_2$ be the lengths of the connector links. Clearly, a configuration of the mechanism can be described by the tuple $q = (y_A,y_B,x_C)$ because $x_A = x_B = y_C = 0$ in any configuration. Since the distances from $A$ to $B$ and from $B$ to $C$ must be kept equal to $L_1$ and $L_2$, Eq. (1) is

$$\begin{aligned}
y_A^2 + x_C^2 &= L_1^2 \\
y_B^2 + x_C^2 &= L_2^2
\end{aligned}$$

(10)

from which we realize that the C-space corresponds to the intersection of two cylinders in the space of $y_A$, $y_B$, and $x_C$.

The velocity equation in Eq. (2) could now be obtained using the revolute- and prismatic-joint screws [18], but a more compact expression can in this case be derived by differentiating Eq. (10). Taking $v_A$ and $v_B$ as the input and output velocities, the differentiation yields

$$Lm = \begin{bmatrix} 0 & 2y_A & 2x_C \\ 2y_B & 0 & 2x_C \\ 2y_B & 2x_C & 0 \end{bmatrix} \begin{bmatrix} v_B \\ v_A \\ v_C \end{bmatrix} = 0,$$

so that $L_I$, $L_O$, and $L_P$ are, respectively,

$$\begin{aligned}
0 & 2x_C \\
2y_B & 2x_C \\
2y_B & 2x_C & 0
\end{bmatrix},
\begin{aligned}
2y_A & 2x_C \\
0 & 2x_C \\
2x_C & 2x_C
\end{aligned},
\begin{aligned}
2x_C & 2x_C
\end{aligned}.$$

Any of the systems in Eqs. (3)-(9) can now be written, and note that they can be solved analytically in this case. For example, if $L_1 = L_2 = 1$, the C-space has a single connected component composed of two ellipses intersecting on the $x_C$ axis (Fig. 2a), and the solutions of the systems in Eq. (3) reveal that the singularity set has six isolated configurations, marked in red in Fig. 2b-bottom, with the following values of $q$:

$$(0,0,1),\ (0,0,-1),\ (-1,-1,0),\ (1,1,0),\ (1,-1,0),\ (-1,1,0).$$
All of these configurations satisfy both systems in Eq. (3), so that both the FIKP and the IIKP are indeterminate in them. It turns out, moreover, that the four configurations with \( x_C = 0 \) satisfy the systems in Eqs. (6), (7) and (8), meaning that they are singularities of IO, II, and RPM type. The other two configurations, which lie in the \( x_C \) axis, are singularities of RI, RO, and IIIM type because they satisfy the systems in Eqs. (4), (5) and (9). These two configurations are in fact \( C \)-space singularities, i.e., points where the tangent space is ill-defined. The \( C \)-space self-intersects at these points, and presents a bifurcation that allows to change the mode of operation from both sliders moving on the same side of the horizontal axis, \( y_A \geq 0 \), to one slider moving on each side, \( y_A \leq 0 \).

The topology of the \( C \)-space changes when \( L_1 \neq L_2 \). It no longer presents any bifurcation, and is instead formed by two connected components (Fig. 2b). By solving Eq. (3) for \( L_1 = 1 \) and \( L_2 = 0.8 \), for example, eight singularities are obtained:

\[
(1, 0.8, 0), \quad (-1, -0.8, 0), \quad (1, -0.8, 0), \quad (-0.6, 0, 0.8), \\
(-1, 0.8, 0), \quad (0.6, 0, -0.8), \quad (0.6, 0, 0.8), \quad (-0.6, 0, -0.8).
\]

As before, the configurations with \( x_C = 0 \) are singularities of IO, II, and RPM type, but the other four configurations are of RO and II type, and there are no singularities of IIIM type. In this case, to change the operation mode from \( y_A \geq 0 \) to \( y_A \leq 0 \) the mechanism has to be disassembled.

It must be noted that if a singularity identification were attempted by means of an input-output velocity equation, for instance \( y_A y_B = y_B^2 \), which holds for all configurations, then the singularities with \( x_C = 0 \) would not be detected.

V. ISOLATING THE SINGULARITY SETS

In the previous example, it was possible to solve all systems in Eqs. (3)-(9) analytically, because they are simple, but this is not the case in general. The need to resort to a numerical method is often imperative in complex manipulators, where such systems are typically big and define positive-dimensional singularity sets. This section provides such a method by adapting a branch-and-prune strategy introduced earlier for position and workspace analysis [25, 26]. The method is based on formulating the systems in a quadratic form, then defining an initial box bounding all points of the solution sets, and finally exploiting the special form of the equations to iteratively remove portions of the box that contain no solution. This approach is advantageous because our solution sets can be of dimensions 0, 1, 2, or higher, and they are defined in the real field. Alternative approaches like homotopy methods are mainly designed to isolate zero- or one-dimensional solutions, and they must compute the roots in the complex field, which may increase the solution dimension unnecessarily [27]. Methods based on elimination exhibit similar drawbacks, and easily explode in complexity with the problem size [28].
A. Equation formulation

In order to formulate the equations, note that the structure of all systems in Eqs. (3)-(9) is very similar. The first line is always Eq. (1), because all solution points must correspond to feasible configurations of the manipulator. The second line always involves $L$ or one of its sub-matrices, and the third line constrains the norm of some vector. For a manipulator involving non-helical lower pairs, the formulation proposed in [25] makes Eq. (1) directly adopt the form of a polynomial system of quadratic equations, and allows writing the components of $L$ using linear terms only [23]. Thus, the second equation of all systems will be quadratic too, and the third equation is directly a quadratic expression. The helical pair could also be treated using the developments in [25], but its treatment is here omitted for ease of explanation.

Written in the previous way, any one of the systems only involves monomials of the form $x_1^2$, or $x_i x_j$, where $x_1$ and $x_j$ refer to any two of their variables. Thus, by introducing changes of variables of the form $x_k = x_1^2$ and $x_l = x_i x_j$, it is possible to expand the systems into the form

$$\begin{align*}
\Lambda(x) &= 0, \\
\Gamma(x) &= 0
\end{align*} \tag{11}$$

where $x$ is a vector encompassing the variables of the original system and the newly-introduced $x_k$ and $x_l$ ones, $\Lambda(x) = 0$ is a collection of linear equations in $x$, and $\Gamma(x) = 0$ is a collection of scalar quadratic equations. In the systems of Eqs. (4)-(7) there is a vector that must be different from zero, but since the technique can also handle non-strict inequalities as explained below, this later condition can be enforced by setting

$$\|\Omega^0\|^2 \geq \epsilon \tag{12}$$

for systems (4) and (7), and

$$\|\Omega^0\|^2 \geq \epsilon \tag{13}$$

for systems (5) and (6), where $\epsilon$ is a sufficiently small value. By using these inequalities, whose terms are also quadratic, some singularities might be overlooked, but $\epsilon$ can be made arbitrarily small, reducing the set of missed solutions to a negligible size.

B. Initial bounding box

It can be shown that all variables in the systems can only take feasible values within bounded intervals. For example, from the results in [25] one can readily define such intervals for the variables in $q$, and the vector in the last line of each system has all of its components in the range $[-1, 1]$. In the case of Eq. (6), the feasibility intervals for the entries of $\Omega^u$ can be readily obtained by mapping the known intervals using $A^u u = \Omega^u$, where $A^u$ is formed by the columns of $L$ corresponding to the output velocity vector. A similar mapping, but using the columns of the input velocity, allows the determination of feasibility intervals for $\Omega^{u\ast}$ in Eq. (7). Finally, by propagating the intervals of the previous variables through the expressions $x_k = x_1^2$ and $x_l = x_i x_j$, it is straightforward to define bounded intervals for the $x_k$ and $x_l$ variables.

In conclusion, from the Cartesian product of all such intervals it is possible to define an initial box $B$ bounding the location of all points $x$ satisfying Eq. (11).

C. Numerical solution

The algorithm for solving Eq. (11), together with Eqs. (12) or (13) in the case of Eqs. (4)-(7), applies two operations on $B$: box shrinking and box splitting. Using box shrinking, portions of $B$ containing no solution are eliminated by narrowing some of its defining intervals. This process is repeated until either (1) the box is found to contain no solution and is marked as empty, (2) the box is “sufficiently” small and can be considered a solution box, or (3) the box cannot be “significantly” reduced. In the latter case, the box is bisected via box splitting and the whole process is recursively applied to the resulting sub-boxes until all box sides are below a given threshold $\sigma$.

The crucial operation in this scheme is box shrinking, which is implemented as follows. The solutions falling in some sub-box $B_i \subseteq B$ must lie in the linear variety defined by $\Lambda(x) = 0$. Thus, we may shrink $B_i$ to the smallest possible box bounding this variety inside $B_i$. The limits of the shrunk box along dimension $x_i$ can be found by solving the linear programs

LP1: Minimize $x_i$, subject to: $\Lambda(x) = 0, x \in B_i$

LP2: Maximize $x_i$, subject to: $\Lambda(x) = 0, x \in B_i$.

However, observe that $B_i$ can be further reduced because the solutions must also satisfy all equations $x_k = x_1^2$ and $x_l = x_i x_j$ in $\Gamma(x) = 0$. These equations can be taken into account by using their linear relaxations [25]. Note that, if $[v_i, u_i]$ denotes the interval of $B_i$ along dimension $x_i$, then:

1) The portion of the parabola $x_k = x_1^2$ lying inside $B_i$ is bound by the triangle $A_1 A_2 A_3$, where $A_1$ and $A_2$ are the points where the parabola intercepts the lines $x_i = v_i$ and $x_i = u_i$, and $A_3$ is the point where the tangent lines at $A_1$ and $A_2$ meet (Fig. 3a).

2) The portion of the hyperbolic paraboloid $x_l = x_i x_j$ lying inside $B_i$ is bound by the tetrahedron $B_1 B_2 B_3 B_4$, where the points $B_1, \ldots, B_4$ are obtained by lifting the corners of the rectangle $[v_i, u_i] \times [v_j, u_j]$ vertically to the paraboloid (Fig. 3b).
Thus, linear inequalities corresponding to these bounds can be added to LP1 and LP2. This usually produces a much larger reduction of $B_{\varepsilon}$, or even its complete elimination if one of the linear programs is found unfeasible. In this step, the inequalities needed to model the conditions in (12) or (13) can also be taken into account by adding them to the linear programs.

As it turns out, the previous algorithm explores a binary tree of boxes whose internal nodes correspond to boxes that have been split at some time, and whose leaves are either solution or empty boxes. The collection $B$ of all solution boxes is returned as output, and it is said to form a box approximation of the singularity set, because it forms a discrete envelope of the set whose accuracy can be adjusted through the $\sigma$ parameter. Notice that the algorithm is complete, in the sense that it will succeed in isolating all solution points accurately, provided that a small-enough value for $\sigma$ is used.

The application of the method to the 3-slider mechanism can be seen in Fig. 4. The figure shows box approximations of the C-space in blue color, obtained by applying the method to Eq. (10) only. The red boxes correspond to singular configurations obtained by solving the systems in Eqs. (4)-(9).

### D. Computational cost

The computational cost of the algorithm can be evaluated by analyzing the cost of one iteration, and the number of iterations to be performed, both in terms of the number of bodies ($n_b$) and joints ($n_j$) of the manipulator. On the one hand, we can consider that an iteration includes the box shrinking process for a given box. This involves solving $2 n_x$ linear programs, where $n_x$ is the number of variables in Eq. (11). Since $n_x$ depends linearly on $n_b$ and $n_j$, and Karmarkar’s bound for the complexity of linear programming is $O(n_x^{3.5})$ [29], we can conclude that the cost of one iteration is worst-case polynomial in $n_b$ and $n_j$. On the other hand, it is difficult to predict how many iterations will be required to isolate all solutions. The number of iterations largely depends on the chosen $\sigma$ and on the dimension $d$ of the singularity subset considered. For $d = 0$ the algorithm is quadratically convergent to the roots. For $d \geq 1$, the cost is inversely proportional to $\sigma$ in the best case. For a fixed $\sigma$, however, the amount of solution boxes grows exponentially with $d$, so that an initial guess on the execution time is usually made on the basis of $d$ only. The value of $d$ can be estimated by noting that the singularity set is typically of codimension one relative to the C-space, and using the Grüber-Kutzbach formula on $n_b$ and $n_j$ to determine the C-space dimension. Detailed properties of the algorithm, including an analysis of its completeness, correctness, and convergence order, are given in [25].

### VI. Test cases

The performance of the approach is next illustrated in two test cases. The results were obtained using a parallelized version of the method implemented in C [30]. Table II summarizes the main performance data on the various singularity sets analyzed. For each set we indicate its dimension ($d$), the number of equations ($N_{eq}$) and variables ($N_{var}$) in its defining system, the number of solution boxes returned by the method ($N_{boxes}$), the accuracy threshold assumed ($\sigma$), the $\epsilon$ parameter where applicable, and the time required to compute the set ($t$), in seconds, on a Xeon processor grid able to run 160 threads in parallel.

### A. A planar manipulator

The 2-DOF mechanism shown in Fig. 5 is used to illustrate the computation of each one of the singularity sets in detail.
The inputs of the manipulator are the joint velocities of $A$ and $E$, and the output is the velocity of point $G$. By gathering the loop-closure equations of the mechanism, and introducing two further equations to include the position of $G$, Eq. (1) can be formulated as follows

$$
\begin{align*}
\cos \theta_A + \cos \theta_B - 2 \cos \theta_D - 1 &= 0 \\
\sin \theta_A + \sin \theta_B - 2 \sin \theta_D &= 0 \\
2 \cos \theta_D + \frac{3}{2} \cos \theta_C + 2 \cos \theta_C - 3 \cos \theta_E - 1 &= 0 \\
2 \sin \theta_D + \frac{3}{2} \sin \theta_C + 2 \sin \theta_C - 3 \sin \theta_E &= 0 \\
x + 2 \cos \theta_D + \frac{3}{2} \cos \theta_C &= 0 \\
y + 2 \sin \theta_D + \frac{3}{2} \sin \theta_C &= 0
\end{align*}
$$

(14)

where $\theta_A$, $\theta_B$, $\theta_C$, $\theta_D$, $\theta_E$ and $\theta_G$ are the counterclockwise angles of links $AB$, $BC$, $CG$, $DC$, $EF$, and $GF$, respectively, relative to the ground, and $x$ and $y$ are the coordinates of point $G$ relative to a fixed frame centered in $D$. The velocity equation of the manipulator may now be obtained by differentiating Eq. (14) with respect to all variables, but it could also be obtained using the twist loop equations, or by any other means. In order to achieve the desired quadratic formulation, the changes of variables $c_\tau = \cos \theta_\tau$ and $s_\tau = \sin \theta_\tau$ can now be applied for all $\tau \in \{A, B, C, D, E, G\}$. Since the variables $c_\tau$ and $s_\tau$ represent the cosine and sine of a variable, the circle equations $c_\tau^2 + s_\tau^2 = 1$ need also to be introduced into the systems, for every angle $\theta_\tau$.

Given that the manipulator has two degrees of freedom, its configuration space is a surface, which is shown projected onto the $x$, $y$, and $\theta_A$ variables in Fig. 6. This surface was obtained from the computation of all solutions of Eq. (1) using the same numerical technique presented in the previous section. Note that by fixing $x$, $y$, and $\theta_A$, there are still two possible positions of point $F$, so that most of the points in this projection correspond, in fact, to two different configurations of the manipulator. Only the points where $E$, $F$, and $G$ are aligned represent a single configuration, and these are exactly the boundaries of the two “holes” that the surface presents.

The singularity set is generally of lower dimension than the configuration space, so that only curves or points are to be expected in the solution set of all systems of equations. The result of the computation of each singularity type is shown in Figs. 7 and 8, projected onto the output and one input ($x$, $y$, $\theta_A$), and onto the output only, respectively. In Fig. 7, the configuration space is shown in blue, separated in two parts so that a cross-section can be seen, but both parts are actually connected through $\pi$ and $-\pi$ as shown in Fig. 6. The gray area in Fig. 8 represents all attainable positions of point $G$, i.e., the workspace of the manipulator.

As it turns out, this manipulator contains no IIM configurations, and the computation of this type of singularity gives no box as output. On the contrary, there are eight distinct RPM singularities, which in these projections appear coincident in pairs as four orange boxes, corresponding to the two possible locations of $F$. Using a different projection, for instance onto $(\theta_A$, $\theta_E$, $\theta_D)$, the eight boxes appear separated.

The green curves correspond to singularities that are both of RI and IO type. These configurations can be seen to contour the two “holes” of the configuration space in this projection. The red curves correspond to configurations simultaneously belonging to the RO and II type. Even if the curves for RI and IO seem to coincide everywhere, there are some IO configurations that are not of RI type, and the same happens for II and RO singularities, respectively. This is illustrated in Fig. 7 with a close-up on the left that shows only the output of computing RI singularities. These gaps on the curves of RI and RO, which can be found by properly adjusting the $\epsilon$ parameter, coincide with the location of the RPM singularities and, hence, the RPM singularities are also of II and IO type (but not of RI or RO type). Fig. 8a shows an example of an (RPM, II, IO) singularity, while Fig. 8b and Fig. 8c show examples of (RI, IO) and (RO, II) singularities, respectively.

Figure 7 also shows yellow (arcs of) curves that correspond to configurations where points $D$, $B$ and $G$ are aligned. For each yellow-marked triple $(x$, $y$, $\theta_A)$, with $D$, $B$ and $G$ collinear, there are two possible locations of point $C$. In contrast, point $C$ is uniquely determined for any other $(x$, $y$, $\theta_A)$. Thus, a point on a yellow curve corresponds to four different
configurations, because each of points $C$ and $F$ can have two positions. As is visible in the figure, these are the points of self-intersection of the projection of the configuration space on the $(x, y, \theta_A)$ space. The four configurations for each point can be identified with the two sides (“in” and “out”) of the two sheets that intersect. The configuration space itself has no self-intersections as there are no configuration-space, or IIM-type, singularities. The yellow points are only singularities of the projection map. The four orange vertices of the yellow curve arcs in Fig. 7 correspond to the eight configurations where $D$, $B$, $G$, and $C$ are collinear. These are the mechanism’s RPM-type singularities. They are branching points for the inverse kinematics solution, because point $C$ can move in two different ways out of such a configuration.
The other configurations where the working mode changes are those where \( E, F, \) and \( G \) are aligned.

Using the same color code, Figs. 9 and 10 show the projection of the results onto the the 3-dimensional space of the two input angles and one passive joint angle \((\theta_A, \theta_E, \theta_D)\) and onto the 2-dimensional input space only. The eight RPM singularities appear separated. As before, for fixed values of \( \theta_A, \theta_E, \) and \( \theta_D \), there are still two possible locations of point \( C \) in general, and almost all points in this projection correspond to two distinct configurations of the manipulator. It can be seen that the configuration space presents four “holes” in these projections. These four contours are made of those configurations where \( G, C, \) and \( F \) are aligned and there is only one possibility for \( C \). Note that none of these “holes” coincides with one in the previous projection, but, once again, crossing each curve allows the transition between two different working modes. One can imagine the two working modes as the two “sides” of the surface of the configuration-space projection. To “get to the opposite side”, i.e., to change working mode, the motion curve must “go through a hole”.

**B. A spatial manipulator**

To illustrate the method on a spatial manipulator, we next apply it to the Stewart-Gough platform. For the sake of conciseness we concentrate on computing the forward singularity locus only, which is the most relevant and representative of the kind of complexity to be confronted in the spatial case. This amounts to formulating and solving the left system in Eq. (3) using the proposed approach.

The platform consists of a moving plate connected to a fixed base by means of six legs, where each leg is a universal-prismatic-spherical chain (Fig. 11, left). The six prismatic joints are actuated, allowing to control the six degrees of freedom of the platform, and the remaining joints are passive [31].

The assembly constraints can be formulated as follows. Let \( A_i \) and \( B_i \) be the center points of the universal and spherical joints. Let also \( \mathcal{F}_1 \) and \( \mathcal{F}_2 \) be fixed and mobile reference frames, centered in \( O \) and \( P \) respectively. Then, the constraints imposed by each leg on the moving plate can be written as

\[
p^{\mathcal{F}_1} = a_i^{\mathcal{F}_1} + d_i d_i^{\mathcal{F}_1} - R b_i^{\mathcal{F}_2},
\]

(15)

\[
\|d_i^{\mathcal{F}_1}\|^2 = 1,
\]

(16)

where \( p^{\mathcal{F}_1}, a_i^{\mathcal{F}_1}, \) and \( b_i^{\mathcal{F}_2} \) are the position vectors of points \( P, A_i, \) and \( B_i \) in the indicated frames, and \( d_i^{\mathcal{F}_1} \) is a
unit vector along the \( i \)-th leg, expressed in frame \( F_1 \). Also, \( d_i \)
the length of the leg, representing the displacement of the
prismatic joint, and \( \hat{R} \) is the rotation matrix providing the
orientation of \( F_2 \) relative to \( F_1 \). The pose of the platform is
given by \( (p^{F_1}, R) \).

In this case, Eq. (1) is the system formed by Eqs. (15) and (16) for all legs, together with the conditions
\[
\|s\|^2 = 1, \quad s \cdot t = 0, \\
\|u\|^2 = 1, \quad s \times t = w_i,
\]
which force \( R = [s, t, w] \) to represent a valid rotation.

The velocity equation can be obtained by writing the expression of the output twist \( \hat{T} \) following each leg
\[
\hat{T} = \Omega^a_i \hat{S}^a_i + \sum_{j=1}^{5} \Omega^p_{i,j} \hat{S}^p_{i,j},
\]
where \( \hat{S}^a_i \) and the \( \hat{S}^p_{i,j} \) are the unit twists of the active and the
five passive joints of the \( i \)-th leg, respectively. By gathering
Eqs. (17) for all legs, we obtain a \( 36 \times 42 \) matrix \( \hat{L} \), and a
velocity vector \( \hat{m} \) containing the six components of the output
twist, the six active velocities of the prismatic joints, and the
30 passive joint velocities of the universal and spherical
joints. This results in a relatively large system of equations,
but by multiplying each side of Eq. (17) by a unit screw
reciprocal to all passive joint twists of the leg, we can conclude
that the forward singularities are the configurations for which
the conventional screw Jacobian \( J \) is singular \([18, 32]\). This
condition is advantageous because \( J \) is only \( 6 \times 6 \), and
generally produces a much smaller system.

For some configurations, the space of reciprocal screws of
a given leg may be of dimension larger than one, and Eq. (17)
should be multiplied by a whole basis of reciprocal screws of
the leg \([33]\). In the Stewart-Gough platform this can only
happen when the center of the leg’s spherical joint is in the
plane of the two revolute-joint axes of the universal joint,
resulting in a singularity of RPM type. Since joint limits and
other constraints typically exclude such singularities in real
platforms, we will not compute them here.

Two slices of the forward singularity locus are shown in
Fig. 11, computed at a constant orientation and at a constant
position of the platform. Alternative slices could also be
obtained if desired, simply by fixing a different set of pose pa-

\[
\text{VII. Conclusions}
\]

This paper has proposed a method for the numerical compu-
tation and detailed classification of the entire singularity set of
a lower-pair manipulator with arbitrary geometry. Systems of
equations have been defined to compute the set, and each one
of the singularity subsets identified in \([18]\). To solve any of the
systems, a numerical method based on linear relaxations has
been proposed, which can obtain a box approximation of the
solution set with the desired accuracy, even in the presence of
self-intersections or dimension changes in the set \([23, 34]\). The
results in Table II we note that it is computationally much harder to
calculate the constant position slice. This agrees with the fact
that the system to be solved is much larger, and its equations
are highly non-linear, in comparison to those of the constant
orientation slice.
REFERENCES

Oriol Bohigas received the double M.S. degree in Mechanical Engineering from the Universitat Politècnica de Catalunya, Spain, and in Aeronautical Engineering from the Institut Supérieur de l’Aéronautique et de l’Espace (ISAE), France, in 2006. After a research internship at Airbus France, he worked for two years as a space engineer at the Centre National d’Etudes Spatiales (CNES). He recently obtained the Ph.D. degree in Robotics with the Kinematics and Robot Design group of the Institut de Robótica i Informàtica Industrial (IRI, CSIC-UPC). His current research interests include workspace and singularity analysis of robot mechanisms.

Dimitar Zlatanov obtained the Diploma in Mathematics and Mechanics from the University of Sofia, Sofia, Bulgaria, in 1989, and the Ph.D. degree in Mechanical Engineering from the University of Toronto, Canada, in 1998. He has held positions at Laval University, in Quebec City, Canada, the University of Innsbruck, Austria, and Tokyo City University, Japan. He is currently on the faculty of the Department of Mechanical and Energy Engineering of the University of Genoa, Italy. His research interests include the design, kinematics, dynamics and control of mechanisms and robotic systems.
Lluís Ros received the Mechanical Engineering degree in 1992, and the Ph.D. degree (with honors) in Industrial Engineering in 2000, both from the Universitat Politècnica de Catalunya (UPC). From 1993 to 1996 he worked with the Control of Resources Group of the Institut de Cibernètica (Barcelona). He was a visiting scholar at York University (Toronto, 1997), University of Tokyo (Tokyo, 1998), and the Laboratoire d’Analyse et Architecture des Systèmes (Toulouse, 1999). He joined the Institut de Robòtica i Informàtica Industrial (IRI, CSIC-UPC) in 1997, where he is currently an Associate Researcher of the Spanish National Research Council (CSIC) since 2004. His research interests include geometry and kinematics, with applications to robotics, computer graphics, and machine vision.

Montserrat Manubens received the Mathematics degree from the Universitat de Barcelona in 2001, and the Ph.D. degree (with honors) in Computer Algebra from the Universitat Politècnica de Catalunya in 2008. From 2009 to 2010 she worked with the Robotics Group of the Institut de Recherche en Communications et Cybernétique de Nantes (France) in the analysis of cuspidal robots. Since 2011 she holds a Juan de la Cierva contract at the Institut de Robòtica i Informàtica Industrial, (IRI, CSIC-UPC). Her current research interests include mathematics and kinematics, with applications to robotics.

Josep M. Porta received the Engineering degree in Computer Science in 1994, and the Ph.D. degree (with honors) in Artificial Intelligence in 2001, both from the Universitat Politècnica de Catalunya, Spain. From 2001 to 2003 he held a postdoctoral position at the University of Amsterdam, doing research in autonomous robot localization using vision. Currently, he is an Associate Researcher of the Spanish National Research Council at the Institut de Robòtica i Informàtica Industrial (IRI, CSIC-UPC), Barcelona, Spain. His current research interests include planning under uncertainty and computational kinematics.
