We present an advanced design methodology for pulse-width-modulated (PWM) DC-AC signal generation. Using design methods based on the Walsh transform, AC sinusoidal signals can be approximated by suitable PWM signals. For different AC amplitudes, the switching instants of the PWM signals can be efficiently computed by using appropriate systems of explicit linear equations. However, the equation systems provided by conventional implementations of this approach are typically only valid for a restricted interval of AC amplitudes and, in general, a supervised implementation of several equation systems is necessary to cover the full AC amplitude range. Additionally, obtaining suitable equation systems for designs with a large number of switching instants requires solving a complex optimization problem. In defining the constitutive pulses of a PWM signal, a suitable partition of the time interval is used as a reference system. In the new methodology, pulses are chosen to be symmetric with respect to the partition points, and the switching times are specified by means of switching ratios with respect to the endpoint subintervals. This approach leads to particularly simple Walsh series representations, introduces a remarkable computational simplification, and achieves excellent results in reducing the harmonic distortion.

1. Introduction

Pulse-width-modulated (PWM) signals are a class of two-value piecewise functions that change values at a set of controlled switching instants $t_i^{(s)}$. One important field of application of PWM signals is the generation of alternating current (AC) from direct current (DC) sources by means of electronic circuits called inverters [1–3]. More precisely, voltage PWM inverters use suitable switching signals to produce a sinusoidal AC voltage, with the desired amplitude and frequency, from a constant DC voltage source. The structure of a voltage PWM inverter is schematically depicted in Figure 1. In the practical implementation of this approach, two important design challenges arise: (i) fast and efficient algorithms are required for adaptive real-time computation of the switching instants $t_i^{(s)}$, and (ii) harmonic distortion must be selectively reduced to produce a high-quality AC signal.

A first attempt to deal with these design problems is provided by the method of programmed harmonic elimination [4–8]. This method, however, presents the serious drawback of having to solve nonlinear equation systems. Some efforts to simplify these systems have been made in [9–12], and soft computing strategies have been considered in [13–17]. Nevertheless, determining a proper initial estimate for the switching times still remains as an unsolved difficulty.

A second line of solution is based on Walsh series representations. The orthogonal systems of Walsh functions [18–20] allow to establish an elegant link between the switching
times $t_i^{(s)}$ and the harmonic amplitudes of a PWM signal [21, 22]. By taking advantage of this link, it is possible to give satisfactory responses to the design challenges: (i) systems of simple linear equations

$$\mathcal{L} = \left\{ t_i^{(s)} = p_i A_{ac} + r_i, \quad i = 1, \ldots, 2M \right\},$$

(1)
can be obtained for fast on-line computation of the switching instants $t_i^{(s)}$ for a given AC amplitude $A_{ac}$ and, simultaneously, (ii) selective elimination of undesirable harmonics can be carried out.

This line of work is started in [23] and extended in [24–26], where the main elements of what we call conventional design method are presented. In this case, the main drawback is that the linear systems $\mathcal{L}$ are only valid for a restricted interval of AC amplitudes and, in general, a supervised implementation of several linear systems $\mathcal{L}$ is necessary to cover the full AC amplitude range. Moreover, obtaining suitable systems $\mathcal{L}$ for a large number of switching instants requires solving a complex optimization problem.

The objective of this paper is to present an improved version of the conventional design method that produces linear systems $\mathcal{L}$ valid for larger AC amplitude ranges. The new method, that we call advanced design method, also introduces a significant computational simplification and, moreover, presents interesting regularity patterns that make it possible to identify efficient design strategies for problems with a large number of switching instants. Some preliminary and partial results related to the improved method have been presented in [27–30].

The paper is organized as follows. In Section 2, some basic notations and fundamental theoretical elements are provided. In Section 3, the conventional design method is formulated in terms of switching ratios, and the main elements of the advanced design method are introduced. In Section 4, the problem of obtaining optimal switching strategies is discussed. Finally, conclusions are presented in Section 5.

2. Theoretical Background

In this section, we provide some notations and theoretical elements that facilitate a clear presentation of the design methodologies discussed in the paper. In particular, we include a detailed discussion of Walsh series representations for signals with quarter-wave odd symmetry and their relation with the corresponding Fourier series representations.

The system of Walsh functions in $[0, T)$

$$\mathcal{W}_T = \{ \text{wal}^T_n(n, t), \quad n \in \mathbb{N}_0 \}$$

(2)
is a sequence of rectangular functions that alternate the values $\pm 1$ and take the value 0 at the discontinuities, which are always located at points of the form $t = (kT)/2^p$. In this work, the functions $\text{wal}^T_n(n, t)$ are arranged in the increasing sequence-order, where the index $n$ indicates the number of changes of sign. The first 16 elements of $\mathcal{W}_T$ are schematically depicted in Figure 2, where the line with label $\text{wal}_n$ corresponds to the graphic of the function $\text{wal}^T_n(n, t), 0 \leq n \leq 15$. For example, the line with label $\text{wal}_2$ corresponds to the Walsh function $\text{wal}^T_2(1, t)$, which takes the value +1 in $[0, T/2)$, the value $-1$ in $(T/2, T)$, and has a change of sign at $t = T/2$. $\mathcal{W}_T$ is a complete and orthogonal system in $[0, T)$. Absolutely integrable functions in $[0, T)$ can be represented in the form of Walsh series

$$f(t) = \sum_{n=0}^{\infty} w_n \text{wal}^T_n(n, t),$$

(3)

with

$$w_n = \frac{1}{T} \int_0^T f(t) \text{wal}^T_n(n, t) \, dt.$$  

(4)

For $T = 1$, we obtain the system of normalized Walsh functions

$$\mathcal{W}_1 = \{ \text{wal}_n(n, t), \quad n \in \mathbb{N}_0 \},$$

(5)

which is a complete and orthonormal system in $[0, 1)$. Arbitrary functions $\text{wal}^T_n(n, t)$ can be expressed in terms of normalized functions in the form

$$\text{wal}^T_n(n, t) = \text{wal}_1 \left( n, \frac{t}{T} \right).$$

(6)

By introducing the normalized time $\tau = t/T$, the coefficients in (4) can be computed as

$$w_n = \int_0^1 f(T\tau) \text{wal}_1(n, \tau) \, d\tau,$$

(7)

and a function $f(t)$ defined in $[0, T)$ can be represented as a normalized Walsh series in the form

$$f(t) = \sum_{n=0}^{\infty} w_n \text{wal}_1 \left( n, \frac{t}{T} \right).$$

(8)

A signal $f(t)$ has quarter-wave odd (QWO) symmetry in the interval $[0, T]$ if $f(t)$ presents odd symmetry with respect to $t = T/2$ in the interval $[0, T)$, and it also has even symmetry with respect to $t = T/4$ in the interval $[0, T/2)$. The system of sinusoidal signals

$$s_T(2k - 1, t) = \sin \left[ (2k - 1) \omega_0 t \right], \quad k = 1, 2, \ldots,$$

(9)
with \( \omega_0 = 2\pi/T \), and the system of Walsh functions

\[
\text{wal}_T (4n - 3, t), \quad n = 1, 2, \ldots
\]

have QWO symmetry in \([0, T)\). Signals \( f(t) \) that are absolutely integrable in \([0, T)\), and present QWO symmetry in the interval, can be represented by a Fourier series of the form

\[
f(t) = \sum_{k=1}^{\infty} a_{2k-1} \sin \left[ (2k - 1) \frac{\omega_0 t}{T} \right],
\]

where

\[
a_{2k-1} = \frac{2}{T} \int_0^T f(t) \sin \left[ (2k - 1) \frac{\omega_0 t}{T} \right] dt
\]

\[
= \frac{8}{T} \int_0^{T/4} f(t) \sin \left[ (2k - 1) \frac{\omega_0 t}{T} \right] dt.
\]

Analogously, \( f(t) \) can be represented by a Walsh series of the form

\[
f(t) = \sum_{n=1}^{\infty} w_{4n-3} \text{wal}_T (4n - 3, t),
\]

where

\[
w_{4n-3} = \frac{1}{T} \int_0^T f(t) \text{wal}_T (4n - 3, t) dt
\]

\[
= \frac{4}{T} \int_0^{T/4} f(t) \text{wal}_T (4n - 3, t) dt.
\]

Let us now consider the \( N \)-term truncated Walsh series

\[
f_N(t) = \sum_{n=1}^{N} \tilde{w}_n \text{wal}_T (4n - 3, t).
\]

Clearly, \( f_N(t) \) has QWO symmetry and can be represented by the Fourier series

\[
f_N(t) = \sum_{k=1}^{\infty} \tilde{a}_k \sin \left[ (2k - 1) \frac{\omega_0 t}{T} \right],
\]

with

\[
\tilde{a}_k = \frac{8}{T} \int_0^{T/4} f_N(t) \sin \left[ (2k - 1) \frac{\omega_0 t}{T} \right] dt.
\]

Note that, for simplicity, we have introduced the notations \( \tilde{w}_n = w_{4n-3} \) and \( \tilde{a}_k = a_{2k-1} \) in (15) and (16), respectively. By substituting (15) in (17), we obtain

\[
\tilde{a}_k = \sum_{n=1}^{N} b_{k,n} \tilde{w}_n,
\]

where

\[
b_{k,n} = \frac{8}{T} \int_0^{T/4} \text{wal}_T (4n - 3, t) \sin \left[ (2k - 1) \frac{\omega_0 t}{T} \right] dt.
\]

Using the \( K \times N \) matrix

\[
B_{K,N} = [b_{k,n}]_{k=1,\ldots,K; n=1,\ldots,N}
\]

the vector of Fourier coefficients

\[
\vec{A}_K = [\tilde{a}_1, \ldots, \tilde{a}_K]^T
\]

can be easily computed from the vector of Walsh coefficients

\[
\vec{W}_N = [\tilde{w}_1, \ldots, \tilde{w}_N]^T
\]

in the form

\[
\vec{A}_K = B_{K,N} \vec{W}_N.
\]

It is worth to be noted that, by considering the property given in (6) and the angles

\[
\alpha = \frac{2\pi}{T} t,
\]

a period-independent expression for the coefficients \( b_{k,n} \) can be obtained in the form

\[
b_{k,n} = \frac{4}{\pi} \int_0^{\pi/2} \text{wal}_{2\pi} (4n - 3, \alpha) \sin \left[ (2k - 1) \frac{\alpha}{2} \right] d\alpha.
\]

Thus, for example, to compute the element \( b_{2,4} \) we only have to consider the nonzero values of the Walsh function \( \text{wal}_{2\pi}(13, \alpha) \) in the quarter-period interval \([0, \pi/2)\)

\[
\text{wal}_{2\pi}(13, \alpha) = \begin{cases}
1, & 0 < \alpha < \frac{\pi}{8}, \\
-1, & \frac{\pi}{8} < \alpha < \frac{\pi}{4}, \\
1, & \frac{\pi}{4} < \alpha < \frac{3\pi}{8}, \\
-1, & \frac{3\pi}{8} < \alpha < \frac{\pi}{2}.
\end{cases}
\]
Figure 3: Bipolar pulse-width-modulated signal with amplitude $V_{dc}$ and switching time instants $t^{(s)}_i$.

The particular values corresponding to the matrix $B_{4,8}$ are displayed in (28)

$$B_{4,8} = \begin{bmatrix}
1.2732 & -0.5274 & -0.1049 & -0.2533 & -0.0249 & 0.0103 & -0.0519 & -0.1254 \\
0.4244 & 1.0246 & -0.6846 & 0.2836 & -0.0860 & -0.2077 & -0.3108 & 0.1287 \\
0.2547 & 0.6148 & 0.9201 & -0.3811 & -0.2037 & -0.4918 & 0.3286 & -0.1361 \\
0.1819 & -0.0753 & 0.3788 & 0.9144 & -0.7505 & 0.3109 & 0.0618 & 0.1493
\end{bmatrix}.$$  (28)

The conventional design method described in Section 3.1 allows to obtain systems of linear equations

$$\mathcal{L}_c = \{t^{(s)}_i = p_i A_{ac} + r_i, \ i = 1, \ldots, 2M\},$$  (34)

which, for a given AC amplitude $A_{ac}$, make possible to compute a suitable PWM signal $f(t)$ satisfying the design conditions (C1)–(C3). However, it must be highlighted that the linear systems $\mathcal{L}_c$ provided by this approach are typically only valid for a restricted range of AC amplitudes

$$[A_{\mathcal{L}}]_{\text{min}} < A_{ac} < [A_{\mathcal{L}}]_{\text{max}}$$  (35)

and, consequently, a supervised implementation of several linear systems can be necessary to cover the full sinusoidal amplitude range.

The advanced design method, presented in Section 3.2, introduces a clever modification in the conventional method that facilitates producing linear systems $\mathcal{L}_a$ with larger amplitude ranges. The new approach also introduces a significant computational simplification and, moreover, presents interesting regularity patterns that make it possible to identify efficient design strategies for large dimension problems.

The formulation of the conventional design method presented in this paper is based on the switching ratios with respect of the interval endpoint, which allow an elegant formulation of the conventional method and leads naturally to the new one.

Remark 1. Unipolar PWM signals, which take the values $V_{dc}$ and 0, are also used in PWM DC-AC signal generation. In this paper, the discussion will be focused on bipolar signals. A detailed account of the unipolar case can be found in [26].
Remark 2. Note that the relative importance of the harmonic amplitude $\phi_{2n-1}$ in the distortion factor (33) decreases with the harmonic order. This is a convenient property for a wide class of practical applications, where the negative effects of the harmonics decrease with the harmonic order.

Remark 3. Some applications can require fast variations of the AC amplitude; consequently, the real-time computation of the PWM switching instants $t_{i}^{(d)}$ will demand simple and highly effective numerical procedures.

3.1. Conventional Design Method. Let us assume that the interval
\[ 0 \leq A_{ac} \leq A_{ac}^* \]
defines the operational range of the sinusoidal amplitude $A_{ac}$ in (29). Let us also consider the signal
\[ f(t) = V_{dc} \tilde{f}(t), \]
where $V_{dc} = A_{ac}^*$ is the DC amplitude, and $\tilde{f}(t)$ is an amplitude-normalized PWM signal that takes the values $\pm 1$ and has QWO symmetry in $[0, T]$. To satisfy the approximation criteria (C1) and (C2), the conventional design method uses PWM signals $\tilde{f}(t)$ with $M$ switching cycles (pulses) in the quarter-wave interval $[0, T/4)$. The $i$th switching cycle starts at the switching-down instant $t_{i}^{(d)}$, where the signal $\tilde{f}(t)$ shifts from $+1$ to $-1$, and ends at the switching-up instant $t_{i}^{(u)}$, where the signal shifts back from $-1$ to $+1$. The switching instants are selected according to the following rules:

(R1) The quarter-wave interval $[0, T/4)$ is divided into $N = 2^p$ intervals
\[ I_j = [t_{j-1}^{(d)}, t_{j}^{(d)}], \quad j = 1, \ldots, N, \]
where the partition points are
\[ t_j = jh, \quad j = 0, \ldots, N, \quad h = \frac{T}{4N}, \]
and $p$ is the smallest integer that satisfies
\[ N = 2^p \geq 4M. \]

(R2) A system of $M$ indexes is chosen as
\[ j^{(d)} = [j_1^{(d)}, \ldots, j_M^{(d)}], \quad 1 \leq j_1^{(d)} < \cdots < j_M^{(d)} \leq N, \]
and a switching-down time is selected in each interval
\[ t_{i}^{(d)} \in I_{j_i^{(d)}}, \quad i = 1, \ldots, M. \]

(R3) The $M$ switching-up instants, $t_{i}^{(u)}$, $i = 1, \ldots, M$, are computed as follows:
\[ t_{i}^{(u)} = \begin{cases} t_{j_i^{(d)}+1}^{(d)} & \text{if } j_i^{(d)} \leq \frac{N}{2}, \\ t_{j_i^{(d)}}^{(d)} & \text{if } \frac{N}{2} \leq j_i^{(d)}. \end{cases} \]

(R4) Each interval $I_j$, $1 \leq j \leq N$, can contain at most one switching time $t_{i}^{(d)}$ or $t_{i}^{(u)}$.

Using the switching ratios with respect to the interval endpoint
\[ \phi_i = \frac{t_{j_i^{(u)} - t_{j_i^{(d)}}}}{h}, \quad i = 1, \ldots, M, \quad h = \frac{T}{4N}, \tag{44} \]
the switching-down instants can be expressed in the form
\[ t_{i}^{(d)} = (j_i^{(d)} - \phi_i)h, \quad i = 1, \ldots, M. \tag{45} \]

In the conventional method, the switching-up instants $t_{i}^{(u)}$ are independent of $\phi_i$ and can be written in terms of the step $h$ as
\[ t_{i}^{(u)} = (j_i^{(d)} + \lambda_i)h, \quad \lambda_i = \begin{cases} 1 & \text{if } j_i^{(d)} < \frac{N}{2}, \\ 0 & \text{if } \frac{N}{2} \leq j_i^{(d)}. \end{cases} \tag{46} \]

A PWM signal $\tilde{f}(t)$, designed according to the rules (R1)–(R4), is schematically displayed in Figure 4. In this case, we have $M = 2$ switching cycles. The interval $[0, T/4)$ is divided into $N = 2^3 = 4M$ subintervals, with step $h = T/32$. The switching-down indexes are $j_1^{(d)} = 3$ and $j_2^{(d)} = 7$. The ratio $\phi_1$ defines the switching-down instant $t_1^{(d)} = (3 - \phi_1)h$; as $j_1^{(d)} < N/2$, the corresponding switching-up instant is located at $t_1^{(u)} = 4h$. The ratio $\phi_2$ defines $t_2^{(d)} = (7 - \phi_2)h$. Now, $N/2 \leq j_2^{(d)}$ and the associated switching-up instant is $t_2^{(u)} = 7h$.

For the PWM signal $\tilde{f}(t)$, defined by the system of switching indexes
\[ j^{(d)} = [j_1^{(d)}, \ldots, j_M^{(d)}], \tag{47} \]
and the vector of switching ratios
\[ \Phi_M = [\phi_1, \ldots, \phi_M]^T, \tag{48} \]
let us consider the truncated Walsh series
\[ \tilde{f}_N(t) = \sum_{n=1}^{N} \bar{v}_n \text{wal}_T(4n - 3, t), \tag{49} \]
where $N = 2^p \geq 4M$ is the number of subintervals in $[0, T/4)$. Taking into account that the Walsh functions $\text{wal}_T(j, t)$ with $j < 2^2$ are constant in the intervals
\[ I_j = [(j - 1)h, jh), \quad j = 1, \ldots, 2^2, \quad h = \frac{T}{2^3}, \tag{50} \]
and observing that
\[ 4N - 3 = 4 \cdot 2^p - 3 < 2^{p+2}, \tag{51} \]
it follows that the Walsh functions
\[ \text{wal}_T(4n - 3, t), \quad n = 1, \ldots, N \tag{52} \]
Figure 4: Switching structure in the conventional design method. In this case, pulses are not symmetric with respect to the partition points.

are constant in the interior points of the intervals \( I_j \) defined in the rule (R1). From (14), the coefficient \( \hat{w}_n \) in (49) can be computed as

\[
\hat{w}_n = \frac{4}{T} \int_0^{T/4} \tilde{f}(t) \operatorname{wal}_T(4n-3,t) \, dt
\]

\[
= \frac{4}{T} \sum_{j=1}^{N} \operatorname{wal}_T(4n-3,j\tau_j) \int_{(j-1)\tau_j}^{j\tau_j} \tilde{f}(t) \, dt,
\]

where \( h = T/(4N) \), and \( \tau_j \in ((j-1)h,jh) \). Using the normalized time \( \tau = t/T \), we can obtain the following period-free expression for \( \hat{w}_n \):

\[
\hat{w}_n = 4 \sum_{j=1}^{N} \operatorname{wal}_1(4n-3,j\tau_j) \int_{(j-1)h}^{j\tau_j} \tilde{f}(\tau T) \, d\tau,
\]

with \( \tau_j \in ((j-1)/4N, j/4N) \). By computing the integrals in (54), we get

\[
\hat{w}_n = - \frac{2}{N} \sum_{j=1}^{M} \phi_j \operatorname{wal}_1(4n-3,j\tau_j) + \frac{1}{N} \sum_{j=1}^{N} \operatorname{wal}_1(4n-3,j\tau_j)
\]

\[
- \frac{2}{N} \sum_{j=1}^{M} \lambda_j \operatorname{wal}_1(4n-3,j\tau_{j(0)}).
\]

The vector of Walsh coefficients

\[
\hat{W}_N = [\hat{w}_1, \ldots, \hat{w}_N]^T
\]

admits the matrix expression

\[
\hat{W}_N = C_{N,M} \hat{A}_M + D_N,
\]

where \( C_{N,M} \) is a matrix with elements

\[
c_{ni} = - \frac{2}{N} \operatorname{wal}_1(4n-3,j\tau_{j(0)}),
\]

\[
n = 1, \ldots, N, \; i = 1, \ldots, M,
\]

\[
d_N = [d_1, \ldots, d_M]^T
\]

is a vector with elements

\[
d_n = \frac{1}{N} \left[ \sum_{j=1}^{N} \operatorname{wal}_1(4n-3,j\tau_j) - 2 \sum_{j=1}^{M} \lambda_j \operatorname{wal}_1(4n-3,j\tau_{j(0)}) \right].
\]

According to the discussion in Section 2, the vector

\[
\hat{A}_M = [\hat{a}_1, \ldots, \hat{a}_M]^T,
\]

which contains the first \( M \) coefficients of the Fourier series representation

\[
\tilde{f}_N(t) = \sum_{k=1}^{\infty} \hat{a}_k \sin((2k-1)\omega_0 t),
\]

can be computed in the form

\[
\hat{A}_M = B_{M,N} \hat{W}_N,
\]

and considering (57), we obtain

\[
\hat{A}_M = E \Phi_M + F,
\]

with

\[
E = B_{M,N} C_{N,M}, \quad F = B_{M,N} D_N.
\]

For the sinusoidal signal (29), let us consider a given AC amplitude \( 0 \leq A_{ac} \leq A^{*}_{ac} \) and the system of switching indexes (41). If there exists a vector of switching ratios

\[
\Phi_M = [\phi_1, \ldots, \phi_M]^T, \quad \phi_i \in (0, 1), \quad i = 1, \ldots, M,
\]

that satisfies

\[
\Phi_M = E^{-1} \left( \hat{A}_M - F \right)
\]

with

\[
\hat{A}_M = [\hat{a}_1, 0, \ldots, 0]^T, \quad \hat{a}_1 = A_{ac}^{*}/A_{ac}^{*},
\]

then the conditions (C1) and (C2) are satisfied by the signal

\[
f(t) = V_{dc} \tilde{f}(t),
\]

where \( V_{dc} = A_{ac}^{*} \) and \( \tilde{f}(t) \) is the amplitude-normalized PWM signal defined by the switching instants (45) and (46), corresponding to the switching ratios (65).

To illustrate the implementation of the conventional method, let us consider the problem of regulating the fundamental amplitude and canceling the first nonfundamental harmonic. In this case, \( M = 2 \) and the number of subintervals in \([0, T/4)\) is \( N = 8 \). For the particular system of switching indexes

\[
j^{(d)} = [j_1^{(d)} = 3, j_2^{(d)} = 7],
\]

and

\[
j^{(u)} = [j_1^{(u)} = 4, j_2^{(u)} = 5, j_3^{(u)} = 8],
\]
3.2. Advanced Design Method. In the new approach, the design of the normalized PWM signal \( \tilde{f}(t) \) is carried out following the same rules (R1), (R2), and (R4) used in the conventional method, but in this case, the switching indexes \( j_i^{(d)} \) satisfy

\[
1 \leq j_1^{(d)} < \cdots < j_M^{(d)} < N,
\]

and the switching-down instants

\[
t_i^{(d)} = (j_i^{(d)} - \phi_i) h, \quad i = 1, \ldots, M
\]

are followed by the switching-up instants

\[
t_i^{(a)} = (j_i^{(d)} + \phi_i) h, \quad i = 1, \ldots, M.
\]

This new switching scheme is displayed in Figure 5, where the symmetrical arrangement of the switching instants \( t_i^{(d)} \) and \( t_i^{(a)} \) with respect to the interval endpoint \( t_i^{(d)} \) can be clearly appreciated. The coefficients (54) of the truncated Walsh series (49) have now the form

\[
\tilde{w}_n = -\frac{2}{N} \sum_{j=1}^{M} \phi_1 \left[ \text{wal}_1 \left( 4n - 3, \tilde{t}_j^{(a)} \right) + \text{wal}_1 \left( 4n - 3, \tilde{t}_j^{(c)} \right) \right]
\]

\[
+ \frac{1}{N} \sum_{j=1}^{N} \text{wal}_1 \left( 4n - 3, \tilde{t}_j \right).
\]

The vector of Walsh coefficients (56) admits the matrix expression (57), but now the elements of the matrix \( C_{N,M} \) take the form

\[
c_{n,j} = -\frac{2}{N} \left[ \text{wal}_1 \left( 4n - 3, \tilde{t}_j^{(a)} \right) + \text{wal}_1 \left( 4n - 3, \tilde{t}_j^{(c)} \right) \right],
\]

and the elements of the vector \( D_N \) are

\[
d_n = \frac{1}{N} \sum_{j=1}^{N} \text{wal}_1 \left( 4n - 3, \tilde{t}_j \right).
\]

The coefficients \( c_{n,j} \) can be easily computed by considering the \( N \times N \) matrix \( S_N \) with elements

\[
s_{n,k} = \text{wal}_1 \left( 4n - 3, \tilde{t}_k \right), \quad \tilde{t}_k = \left( \frac{k-1}{4N}, \frac{k}{4N} \right).
\]

The \( n \)th row of \( S_N \) contains the sign sequence of the Walsh function \( \text{wal}_1(4n - 3, r) \) for a homogeneous partition of the interval \([0, 1/4)\) with step \( h = 1/(4N) \). Now, we have

\[
c_{n,j} = -\frac{2}{N} \left( s_{n,j^{(a)}} + s_{n,j^{(c)+1}} \right),
\]
and the $i$th column of $C_{N,M}$ can be obtained by adding the columns $j_i^{(d)}$ and $j_i^{(d)}+1$ of $S_N$, and multiplying by $-2/N$. The coefficients $d_n$ can also be expressed in terms of the elements $s_{nk}$ as

$$d_n = \frac{1}{N} \left( \sum_{k=1}^{N} s_{nk} \right)$$  \hspace{1cm} (84)

and could be computed by adding the columns of $S_N$. However, it is not necessary to perform this computation because (81) always produces the vector

$$D_N = [1, 0, \ldots, 0]^T.$$  \hspace{1cm} (85)

Clearly, the rest of the design procedure described in Section 3.1 and the discussion about the regulation range remain valid for the new approach.

To illustrate the implementation of the advanced method, let us consider the design problem presented in the previous section, with $M = 2$, $N = 8$ and the switching indexes $j_1^{(d)} = 3$ and $j_2^{(d)} = 7$. For a homogeneous partition of the interval $[0, 1/4]$ with step $h = 1/32$, the system of Walsh functions

$$\text{wal}_1(1, \tau), \text{wal}_1(5, \tau), \text{wal}_1(9, \tau), \ldots, \text{wal}_1(29, \tau)$$  \hspace{1cm} (86)

produces the matrix of sign sequences

$$S_8 = \begin{bmatrix}
1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\
1 & 1 & 1 & 1 & -1 & -1 & -1 & -1 \\
1 & -1 & -1 & -1 & 1 & 1 & 1 & 1 \\
1 & 1 & -1 & -1 & 1 & 1 & 1 & 1 \\
1 & -1 & -1 & -1 & 1 & 1 & 1 & 1 \\
1 & 1 & -1 & -1 & 1 & 1 & 1 & 1 \\
1 & -1 & -1 & -1 & 1 & 1 & 1 & 1 \\
1 & 1 & -1 & -1 & 1 & 1 & 1 & 1
\end{bmatrix}.  \hspace{1cm} (87)

According to (83), the matrix $C_{8,2}$ is

$$C_{8,2} = -\frac{1}{4} \begin{bmatrix}
2 & -2 & -2 & 0 & 0 & 0 & 0 & 0 \\
-2 & 2 & -2 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0
\end{bmatrix} = -\frac{1}{2} \begin{bmatrix}
1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\
-1 & 1 & -1 & 1 & -1 & 1 & -1 & 1 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0
\end{bmatrix},  \hspace{1cm} (88)

and from (84), the value of $D_8$ is

$$D_8 = \frac{1}{8} \begin{bmatrix}
8 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 0
\end{bmatrix}.$$  \hspace{1cm} (89)

which coincides with the value indicated in (85). Finally, using (64) and (66) with the matrix $B_{2,8}$ introduced in the previous subsection, and the matrices $C_{8,2}$ and $D_8$ given in (88) and (89), we obtain the linear system

$$\mathcal{L}_a = \begin{bmatrix}
\phi_1 = -0.5877\hat{A}_1 + 1.0583, \\
\phi_2 = -0.6933\hat{A}_1 + 0.7071, \\
\end{bmatrix}  \hspace{1cm} (90)$$

and from the associated auxiliary system

$$\mathcal{L}_a' = \begin{bmatrix}
\hat{A}_1 \end{bmatrix} = \begin{bmatrix}
-1.7015\phi_1 + 1.8007, \\
-1.4424\phi_2 + 1.0200, \\
\end{bmatrix}  \hspace{1cm} (91)$$

we get the modulation range

$$[\hat{A}_1]_{\text{min}} = 0.0992, \quad [\hat{A}_1]_{\text{max}} = 1.0200.  \hspace{1cm} (92)$$

This example clearly shows that the advanced design method introduces an important computational simplification. Moreover, by comparing the values in (75) and (92), it can be appreciated that the advanced method also produces significantly larger modulation ranges.

**Remark 4.** The sign sequences generated by the Walsh functions $\text{wal}_1(4n - 3, \tau), n = 1, \ldots, N$, for a homogeneous partition of $[0, 1/4]$ with step $h = 1/(4N)$ are coincident with the sign sequences generated by the Walsh functions $\text{wal}_1(n - 1, \tau), n = 1, \ldots, N$, for a homogeneous partition of $[0, 1]$ with step $h = 1/N$. Considering the property (6), the matrix $S_N$ can be computed by using the sign sequences of the functions $\text{wal}_{\tau}(n - 1, t), n = 1, \ldots, N$, for a homogeneous partition of $[0, T]$ with step $h = T/N$. For example, the matrix $S_8$ presented in (87) can be obtained from the sign sequences of the Walsh functions $\text{wal}_{\tau}(n - 1, t), n = 1, \ldots, 8$, for a homogeneous partition of $[0, T]$ with step $h = T/8$ (see Figure 2).

**Remark 5.** From the previous remark and (84), we have

$$d_n = \sum_{k=1}^{N} \text{wal}_1(n - 1, \bar{t}_k), \quad \bar{t}_k \in \left( \frac{k - 1}{N}, \frac{k}{N} \right)$$  \hspace{1cm} (93)

and from (84), the value of $D_8$ is

In consequence, $d_1 = 1$, and $d_n = 0$ for $n = 2, \ldots, N$, as indicated in (85).

**Remark 6.** Offline computations are carried out to design the linear systems $\mathcal{L}_a$ and $\mathcal{L}_a'$. Then, these linear systems can be used for fast real-time computation of suitable PWM signals.

### 4. Optimal Switching Strategies

According to the results in Section 3, PWM signals with $M = 2^p$ switching cycles in the quarter-period interval can be conveniently designed to modulate the normalized
fundamental-frequency amplitude $\hat{A}_1$ and cancel the first $M - 1$ nonfundamental odd harmonics. In the design procedure, the quarter-period interval is divided into $N = 2^{p+2}$ subintervals, and a suitable system of switching indexes

$$J^{(d)} = [j_1^{(d)}, \ldots, j_M^{(d)}]$$

(94)

is selected. Each system $J^{(d)}$ determines a PWM signal $\hat{f}(t)$ that satisfies the design conditions for a certain normalized-amplitude interval

$$[\hat{A}_1]_{\min} < \hat{A} < [\hat{A}_1]_{\max}.$$  

(95)

Obviously, the interval length

$$\Delta = [\hat{A}_1]_{\max} - [\hat{A}_1]_{\min}$$

(96)

is a meaningful design parameter. Values of $\Delta$ close to 1 indicate designs of practical interest. Additionally, unfeasible designs are obtained for negative values of $\Delta$.

The main objective of this section is to design PWM signals $\hat{f}(t)$ with optimal amplitude ranges (95). For clarity and simplicity, we will initially focus the discussion on signals $\hat{f}(t)$ with $M = 8$ switching cycles in the quarter-period interval. In this case, the interval $[0, T/4)$ is divided into $N = 32$ subintervals as follows:

$$I_j = [(j-1)h, jh), \quad j = 1, \ldots, 32, \quad h = \frac{T}{128}.$$ 

(97)

The design of a specific PWM signal starts by selecting a system of switching indexes

$$J^{(d)} = [j_1^{(d)}, \ldots, j_8^{(d)}],$$

(98)

which determine the starting subintervals for the switching cycles. The number of different index systems $J^{(d)}$ is

$$\binom{32}{8} = 1.05 \times 10^7.$$ 

(99)

This huge number clearly shows that strategies based on exhaustive exploration are not viable, even for moderate values of $M$.

Exploratory studies, conducted with small values of $M$, indicate that constraining the starting point of the switching cycles within blocks of four consecutive subintervals produces no negative effect in the optimization problem. Consequently, the switching indexes $j_i^{(d)}$ can be selected satisfying

$$4i - 3 \leq j_i^{(d)} < 4i + 1, \quad i = 1, \ldots, 8.$$ 

(100)

Under this constrained selection scheme, the number of different systems $J^{(d)}$ is reduced to a more tractable value

$$4^8 = 65536.$$ 

(101)

It should be highlighted, however, that these index systems can be infeasible for a variety of reasons, for example, violating the design rule (R4) or condition (76), or producing negative values for $\Delta$. The numbers of feasible switching index systems obtained with the conventional and advanced design methods are presented in Table 1, which also includes the number of feasible index systems that produce amplitude intervals (95) with length $\Delta$ in the ranges

$$\Delta < 20\%, \quad 20\% \leq \Delta \leq 40\%, \quad \Delta > 40\%.$$ 

(102)

The data in Table 1 clearly indicate the superiority of the advanced method in providing feasible index systems $J^{(d)}$. This superiority is particularly remarkable for large values of $\Delta$.

The optimal index system for the conventional design method is

$$J^{(c)} = [2, 6, 9, 14, 20, 22, 27, 30],$$

(103)

which produces the following system of linear equations to compute the switching ratios:

$$\mathcal{L} = \begin{bmatrix} \phi_1 = -0.1418 \hat{A}_1 + 1.0034, \\ \phi_2 = -0.3350 \hat{A}_1 + 0.9945, \\ \phi_3 = -0.5201 \hat{A}_1 + 1.0077, \\ \phi_4 = -0.8787 \hat{A}_1 + 0.9723, \\ \phi_5 = -1.0310 \hat{A}_1 + 1.0067, \\ \phi_6 = -0.7059 \hat{A}_1 + 0.7071. \end{bmatrix}$$

(104)

The PWM signal and the harmonic distribution obtained for a DC amplitude $V_{dc} = 100$ V, a fundamental frequency of 50 Hz, and the AC amplitude $A_{ac} = 98$ V are displayed in Figure 6. The corresponding switching instants can be computed by setting the normalized amplitude $\hat{A}_1 = 0.98$ in (104), and by considering (45) and (46) with a period $T = 20$ ms. The PWM signal and the harmonic distribution for the same DC amplitude and frequency, and $A_{ac} = 54$ V are displayed in Figure 7.

For the advanced method, we obtain the optimal index system

$$J^{(a)} = [3, 7, 11, 15, 19, 23, 27, 31],$$

(105)
The PWM signals and the harmonic distributions obtained for the DC amplitude $V_{dc} = 100$ V, a fundamental frequency of 50 Hz, and the AC amplitudes $A_{ac} = 98$ V and $A_{ac} = 54$ V are displayed in Figures 8 and 9, respectively. In this case, the switching instants are obtained from the linear system $\mathcal{L}_a$ in (106), (77), and (78).

The values of the optimal amplitude intervals achieved by the conventional and advanced design methods for the optimal switching index systems (103) and (105), respectively, are presented in Table 2. Also in this case, the data show the superiority of the advanced method, which can practically cover the whole modulation interval with a single linear system $\mathcal{L}_a$. In contrast, the best solution provided by the conventional method only covers the normalized amplitude interval 54.7%–98.5%.

Regarding the harmonic distortion, the values of the distortion factor (33) obtained for the optimal advanced design (see DF values in Figures 8 and 9) are inferior to the corresponding ones obtained for the optimal conventional design (see DF values in Figures 6 and 7). Moreover, the harmonic distributions of the optimal advanced design present a very regular pattern, which contrasts sharply with the uneven harmonic distributions of the optimal conventional design.

Finally, one of the most outstanding features of the new approach is that the design methodology discussed for $M = 8$
can be extended to larger values $M = 2^p$ by selecting the system of switching indexes

$$J_M^{(d)} = [j_1^{(d)}, \ldots, j_M^{(d)}], \quad j_i^{(d)} = 4i - 1, \quad i = 1, \ldots, M,$$

(107)

which, using a common computational notation, can be represented in the form

$$J_M^{(d)} = [j_1^{(d)} : 4 : j_M^{(d)}] = [3 : 4 : 4M - 1],$$

(108)

where $j_1^{(d)} = 3$ and $j_M^{(d)} = 4M - 1$ are the first and last elements of the index sequence, respectively, and 4 is the step. The PWM signal and the harmonic distribution obtained in the case $M = 32$ with the index system $J_{32}^{(d)} = [3 : 4 : 127]$, for a fundamental frequency of 50 Hz and $V_{dc} = A_{ac} = 100$ V. This design strategy has been successfully applied to the values $M = 2^p$, $3 \leq p \leq 6$, obtaining in all the cases a normalized-amplitude regulation interval of 5%–100% and the well-shaped harmonic distribution observed in Figures 8, 9, and 10.

Remark 7. The strategy for selective harmonic elimination discussed in Section 3 uses an $N$-term truncated Walsh series (49) to represent the PWM signal. Consequently, condition (32) is only approximately satisfied, and the first $M - 1$ nonfundamental harmonics are not fully eliminated by small values of $M$. This fact can be appreciated in Figures 7–10. For $M = 2^p$, the number of terms in the truncated Walsh series is $N = 2^{p+2}$. Hence, an accurate representation of the PWM signal is obtained by moderate values of $M$, and this residual harmonic distortion is practically removed (see Figure 10).

5. Conclusions

In this paper, an advanced design method for DC-AC signal generation using pulse-width-modulated (PWM) signals has been presented. The new method is based on the Walsh transform and introduces significant improvements with respect to the current design methodologies. In particular, the new approach presents the following features. (i) Efficient real-time operation. The switching instants of the PWM signal can be easily computed by means of explicit linear systems. Moreover, these linear systems are valid for a wide AC-amplitude range. (ii) Improved harmonic distortion attenuation. A prescribed number of initial harmonics can be fully eliminated, and the residual harmonics present a particularly well-shaped distribution. (iii) Large-dimension extensibility. Optimal switching strategies for PWM signals with a large number of pulses can be directly obtained, without solving costly optimization problems.

In this work, the discussion has been focused on the problem of DC-AC signal generation. However, the proposed approach can also be of interest in other fields as, for example, power measurement [31].
