17  
18 **ABSTRACT**

19 A heterogeneous respirometer (HR) was coupled for the first time to a microelectrode  
20 monitoring system specifically designed for dissolved oxygen (DO) measuring within the  
21 biofilm. Monitoring of the oxygen concentration in the gas and liquid phases was  
22 complemented with pioneering monitoring of DO performed simultaneously and  
23 continuously at multiple biofilm depths. A set of respirometric tests performed at neutral  
24 pH and with initial gas phase concentrations of  $H_2S$  ranging from 135 to 6720 ppm<sub>v</sub> were

25 used to assess sulfide-oxidizing activity of a biofilm grown on Pall rings withdrawn from  
26 a biogas desulfurizing biotrickling filter. A mechanistic model for the description of  
27 multi-step sulfide oxidation within a biotrickling filter was improved considering  
28 heterogeneous biomass concentration and biomass activity distribution along the biofilm  
29 depth. A comprehensive description of physical, chemical and biological phenomena  
30 occurring throughout gas, liquid and biofilm phases resulted in an accurate prediction of  
31 system behavior. Model calibration using experimental data estimated a biomass density  
32 from 3200 to 4400 g VSS·L<sup>-1</sup> as well as a decrease in the fraction of active biomass of  
33 0.5, over the 600 μm thick biofilm. Model simulations accurately reproduced  
34 experimental respirometric profiles (NRMSE<10%), demonstrating that coupling HR and  
35 microelectrodes improved model predictions in comparison to sole gas or liquid phase  
36 measurements, thus contributing to a deeper knowledge of biofilms performance in  
37 trickled bed biological systems.

## 43 **1. INTRODUCTION**

44 Biodegradation of pollutants contained in waste gases can be efficiently accomplished  
45 in biotrickling filters (BTFs), a widespread technology that has been applied for a range  
46 of applications from biogas desulfurization to odor removal. The immobilized growth of  
47 the bacteria that form the biofilms allows a high transfer area to gaseous contaminants in  
48 these configurations and brings additional benefits such as good resistance to operational  
49 fluctuations, such as starving periods [1]. Gas-liquid mass transport, diffusion in the  
50 biofilm and biological degradation kinetics have been identified as the most relevant  
51 processes occurring in a BTF [2]. The inherent complexity of such plug-flow,  
52 heterogeneous, multiphase bioreactors requires an accurate characterization of the  
53 physical, chemical and biological phenomena taking place, not only to obtain a proper  
54 description of liquid and gas phase dynamics, but especially to assess the biofilm behavior  
55 in which pollutants biodegradation process takes place.

56 Although gas and liquid phases can be easily monitored during the biofiltration of  
57 gaseous pollutants in BTFs, biofilm performance is difficult to assess since biofilms grow  
58 immobilized over the surface of a packing material [3]. In this sense, a more profound  
59 knowledge of biofilm dynamics would help improve BTFs design and operability to  
60 achieve better performances. To this end, many authors have studied biofilms both  
61 microscopically and macroscopically. Some studies characterized biofilm biodegradation  
62 mechanisms and activity [4–9], while others placed efforts to describe biofilms  
63 development, structure and performance through mathematical modelling [6,10–15].

64 In gas biofiltration, and also in water treatment, biofilms have been usually modelled  
65 through 2D deterministic models that consider biofilms as a planar, stratified phase with  
66 constant physical, chemical and biological characteristics where diffusion and  
67 biodegradation take place [16,17]. However, some authors have applied novel techniques,  
68 such as confocal microscopy and microsensors monitoring to evaluate the internal biofilm  
69 structure and processes taking place, highlighting the deep impact of heterogeneity on  
70 biofilm properties and performance [18–20]. Up to now, some works have included the  
71 effect of biofilm heterogeneity to describe biofilms [21–26]. Nevertheless, improved  
72 models based on data from biofilms are still required to avoid inaccuracies between  
73 experimental observation and model predictions.

74 To this end, some adapted respirometric methodologies have been developed for a  
75 realistic assessment of the biodegradation activity in biofiltration applications [27,28].  
76 The successful implementation of these methods is mainly due to the simplicity and high  
77 sensitivity associated with the monitoring of DO concentration. Bonilla-Blancas et al.  
78 [28] developed a heterogeneous respirometry (HR) methodology based on the monitoring  
79 of DO concentrations when a pulse of substrate was added to a respirometric vessel  
80 mimicking a BTF. The HR was applied to characterize both mass transfer phenomena  
81 occurring within gas (G), liquid (L) and biofilm (B) phases, and the biodegradation  
82 activity in a trickled-bed colonized by a H<sub>2</sub>S-oxidizing biofilm. The HR technique was  
83 demonstrated as a powerful tool to characterize biofilms in a multiphase system, under  
84 tightly controlled conditions, using experimental oxygen profiles from bulk gas and liquid  
85 phases to calibrate a simplified 2D mathematical model. However, their mathematical  
86 model predictions could not be calibrated with experimental biofilm profiling since it was  
87 not monitored, thus leading to large uncertainties in model estimations. The use of biofilm  
88 monitoring tools to obtain experimental data within the biofilm would increase the

89 reliability of the biological activity characterization and of the mathematical models  
90 developed for the description of biofiltration systems description.

91 Biofilms monitoring using microelectrodes has been performed by several authors  
92 reporting successful results. As an example, Zhang and Bishop [9] and De Beer et al. [29]  
93 among other authors [24,30–33], studied the biofilm heterogeneity, mass transfer  
94 resistance and biological activity using different types of microelectrodes. Nowadays,  
95 commercial microsensors, such as Clark-type microelectrodes, are available to monitor  
96 biofilms. However, such microelectrodes pose important drawbacks such as their high  
97 cost and fragility, and the impossibility of performing simultaneous measurements at  
98 multiple biofilm depths. Clark-type microelectrodes do not allow performing multi-point  
99 simultaneous dynamic measurements through biofilms, thus being mainly limited to the  
100 recording of multi-point, steady-state concentration profiles or to single-point dynamic  
101 profiles. During the last years, efforts have been placed to develop different types of  
102 microsensors targeting the monitoring of different parameters, such as DO or pH, in one  
103 single microsensor with the minimal invasion of the monitored media [34,35]. As an  
104 example, an array of gold microelectrodes was developed based on  
105 microelectromechanical systems technology to monitor oxygen consumption in aerobic  
106 heterotrophic biofilms cultivated in a flat plate bioreactor [36]. This microsensor  
107 consisted of an array of eleven microelectrodes distributed in a needle of 1 mm in length.  
108 The simultaneous measurement of DO concentration on the eleven microelectrodes  
109 allowed the simultaneous evaluation of the oxygen distribution over time within multiple  
110 locations in a biofilm. In Guimerà et al. [6], the application of this microsensor to  
111 characterize the biofilm allowed estimating the effective diffusivity within the biofilm, in  
112 addition to the biokinetics of the microbial culture.

113 In the current work, a microsensor specifically designed for biofilm monitoring was  
114 used in an HR to improve the description of functional and structural characteristics of a  
115 sulfide-oxidizing biofilm. To this end, a microsensor multi-electrode design allowing the  
116 dynamic and simultaneous multi-point monitoring of DO concentration through several  
117 biofilm depths [34] was setup in a HR experimental setup to obtain dynamic DO profiles  
118 within a biofilm. In the same way, a mathematical model for the description of H<sub>2</sub>S  
119 oxidation in a BTF [2] was assessed and modified to describe biofilm as a stratified layer.  
120 The suitability of the improved HR to characterize the trickled bed performance, and  
121 specially biofilm activity and dynamics, were evaluated by monitoring the oxidation of

122 H<sub>2</sub>S within the HR. The HR was filled with Pall rings, colonized by a H<sub>2</sub>S-oxidizing  
123 biofilm, obtained from a desulfurizing BTF. The model was calibrated to describe  
124 respirometric tests using experimental data from the dynamic evolution of DO  
125 concentration within the gas phase and the liquid phase, but also from different points  
126 inside the biofilm. Thereby, experimental data obtained under steady-state conditions,  
127 and usually used for biofilm models calibration [26,37–40], was replaced herein for  
128 experimental data obtained under dynamic conditions in order to increase the reliability  
129 of model predictions. Additionally, to the best of authors' knowledge, this is the first time  
130 that a microsensor has been successfully implemented for multi-point, biofilm monitoring  
131 obtaining relevant data in real-time.

132

## 133 **2. MATERIALS AND METHODS**

### 134 **2.1. Heterogeneous respirometer setup**

135 The heterogeneous respirometer setup is shown in Fig. 1a. The respirometer was  
136 designed with an easy-to-open system in order to fill the bed volume (0.63 L) with the  
137 biofilm-covered packing material to be characterized [41]. The heterogeneous  
138 respirometer was manufactured in PVC with a bed diameter and height of 0.059 m and  
139 0.23 m, respectively. The heterogeneous respirometer was prepared to recirculate  
140 counter-currently (downflow) the liquid phase, using a peristaltic pump (77200-12, Cole  
141 Parmer, USA), and the gas phase, using a gas compressor (Model 3112, Boxer, UK). The  
142 system could be operated either as a completely closed system (differential) or as an  
143 opened system with respect to the gas phase by shifting the position of the inlet and outlet  
144 gas valves (Fig. 1a).

145 The monitoring of the oxygen concentration in the gas and liquid phases was  
146 performed through an O<sub>2</sub> sensor (O<sub>2</sub> SL-sensor, Euro-Gas Management Services, UK)  
147 and a galvanic dissolved oxygen sensor (Cellox 325, WTW, Germany), respectively.  
148 Both parameters were measured in the gas and liquid recirculation lines. The pH was also  
149 monitored (Sentix 82, WTW, Germany) in the liquid reservoir. Both the DO sensor and  
150 the pH electrode were connected to a bench-top meter (Inolab Multi 740, WTW,  
151 Germany). The pH was also accurately controlled at  $\text{pH } 7.0 \pm 0.1$  by a high-precision  
152 two-channel micro-burette (Multi-burette 2S, Crison, USA) adding either HCl (1M) or  
153 NaOH (1M) solutions. Sulfate and thiosulfate concentrations were analyzed by ion

154 chromatography with conductivity detection using a Dionex ICS2000 (United States)  
155 equipment. The system was operated at room temperature (between 20°C and 25°C).

## 156 **2.2. DO microsensor**

157 DO concentration within the biofilm was monitored during respirometric tests using a  
158 specifically designed DO microsensor. The DO microsensor was specially designed for  
159 biofilm monitoring as described elsewhere [34]. The DO microsensor consisted of a linear  
160 array of eleven gold-disk electrodes of 50 µm-diameter and separated by 100 µm, and a  
161 rectangular gold one mounted on a minimally invasive micro-fabricated needle (Fig. 1b).  
162 Disk electrodes were designed as working electrodes (WE) or sensing electrodes, while  
163 the rectangular one was designed as counter-electrode (CE). WE were simultaneously  
164 polarized at the oxygen reduction potential [34] (-850 mV) using an 8-channel  
165 potentiostat (1010C, CH-Instruments, USA). Electrodes potential was controlled using  
166 an external reference electrode (RE) (REF321, Radiometer analytical, France). The  
167 electrodes were simultaneously calibrated before biofilm monitoring and the measuring  
168 of reduction currents were used to quantify the DO concentration (further information  
169 about microsensor preparation and calibration is detailed elsewhere [34]).

170 Compared to commercial, Clark-type electrodes, the high robustness of the  
171 microfabricated needle allowed its utilisation for the trickled bed monitoring. To this end,  
172 the microsensor was inserted vertically into the biofilm through the heterogeneous  
173 respirometer monitoring port (Fig. 1c) enabling the simultaneous monitoring of DO  
174 concentration at 8 different well-defined depths within H<sub>2</sub>S-oxidizing biofilm. The  
175 dynamic information of the DO concentration evolution within the biofilm, instead of  
176 steady-state concentration profiles typically recorded using conventional microsensors,  
177 provided a breakthrough approach in the use of HR.

178 Microsensors suitability for H<sub>2</sub>S-oxidizing biofilm monitoring was assessed by  
179 quantifying the drift of sensors response during respirometric tests. To this aim, the  
180 microsensor response was characterized at the beginning and at the end of each  
181 experimental test. Fouling of electrodes over a 4 hour period resulted in a sensitivity  
182 decrease lower than 10%, which was a tolerable loss of sensitivity to perform short-term  
183 monitoring tests according to Moya et al. [34].

## 184 **2.3. Performance of respirometric tests in the HR**

185 The biofilm-covered packing material (plastic Pall rings with a diameter of 15.9 mm)  
186 was obtained from a biogas desulfurizing BTF, which was operated for more than two  
187 years treating an H<sub>2</sub>S inlet concentration of 2000 ppm<sub>v</sub> [41]. Once the packing material  
188 was distributed carefully inside the packed bed container of the heterogeneous  
189 respirometer (Fig. 1a, number 6), the microsensor was inserted within the biofilm through  
190 the monitoring port. Then, the port was sealed using an epoxy resin. Before starting the  
191 respirometric tests, a fresh volume of 126 mL of mineral medium (MM) was added to the  
192 HR. The composition of the MM was (g L<sup>-1</sup>): K<sub>2</sub>HPO<sub>4</sub> (0.15), KH<sub>2</sub>PO<sub>4</sub> (0.12), NH<sub>4</sub>Cl (1),  
193 CaCl<sub>2</sub> (0.02), MgSO<sub>4</sub>·7H<sub>2</sub>O (0.20) and trace elements solution [42] (1 mL L<sup>-1</sup>).  
194 Additionally, sodium bicarbonate was added as the microbial carbon source to the MM  
195 (3.5 g L<sup>-1</sup> NaHCO<sub>3</sub>). The MM was continuously recirculated through the colonized  
196 packing material for 24 hours with continuous aeration to achieve endogenous conditions,  
197 thus ensuring the oxidation of any bioavailable substrates (dissolved sulfide, thiosulfate  
198 and/or elemental sulfur) accumulated within the biofilm. Afterwards, the MM was  
199 renewed, and the heterogeneous respirometer was operated as a closed system (inlet and  
200 outlet liquid or gas flows were not allowed). At this point, the respirometric study was  
201 initialized.

202 Respirometric tests were performed following three basic steps [43]: 1. Calculation of  
203 the endogenous oxygen uptake rate (OUR<sub>end</sub>) from the slope of the DO profile without  
204 bioavailable substrates, 2. Re-aeration of the system and 3. Addition of substrate pulses  
205 to calculate the exogenous oxygen uptake rates (OUR<sub>ex</sub>) associated with each substrate  
206 concentration tested. In this study, different pulses of pure H<sub>2</sub>S were injected in the  
207 heterogeneous respirometer to characterize the biofilm (200 μL, 1 mL, 5 mL and 10 mL).  
208 The pulses corresponded to initial H<sub>2</sub>S gas phase concentrations ranging from 135 to 6720  
209 ppm<sub>v</sub>, which is a concentration range commonly found in biogas desulfurization BTFs.  
210 After spiking the heterogeneous respirometer with each pulse of the substrate, the system  
211 was opened and re-aerated again to reach DO saturation conditions. Gas and liquid phases  
212 were recirculated during the respirometric tests at constant flows to set linear velocities  
213 of 43.4 and 10.8 m h<sup>-1</sup>, respectively. During the overall operation, the oxygen  
214 concentration was simultaneously monitored in all phases (gas, liquid and biofilm).  
215 Experimental data obtained from respirometric tests were used to calibrate the biokinetic  
216 and hydrodynamic mathematical model developed to describe H<sub>2</sub>S biodegradation in this  
217 specific biofilm-covered trickled bed.

## 218        **2.4. Experimental determinations in the heterogeneous respirometer**

219        Additional experimental analyses were performed to calculate relevant parameters for  
220        the mathematical model development. In this sense, the static and dynamic hold-ups, the  
221        fractions of the packed bed occupied by liquid, gas, biofilm and packing material, and the  
222        biofilm content and biomass fraction in the biofilm were determined following the  
223        methodology described in Bonilla-Blancas et al. [28]. Additionally, the amount of  
224        biomass attached to the packing support was quantified following the methodology by  
225        Lazarova and Manem [30] . In short, once the corresponding assay was finished, the liquid  
226        pump was stopped, and the packing material was immediately weighed ( $W_1$ ). After  
227        draining the liquid for a period of 30 minutes, the support was weighed again ( $W_2$ ). The  
228        weight difference between  $W_2$  and  $W_1$  determined the static hold-up that, together with  
229        the dynamic hold-up, was used to estimate the volume fraction occupied by the liquid  
230        ( $\varepsilon_L^{Bed}$ ). Once drained, the packing material was carefully shaken to withdraw all the  
231        biofilm and then was re-suspended in a known volume of water. The clean packing was  
232        dried for 12 hours at 50 °C to determine the weight of the support ( $W_3$ ). The suspended  
233        biomass was later centrifuged at 5000 rpm for 10 minutes and the supernatant was  
234        discarded to determine the weight of wet biomass ( $W_4$ ). The volume fraction occupied by  
235        the biofilm ( $\varepsilon_B^{Bed}$ ) was calculated by dividing  $W_4$  by the product of wet biofilm density  
236        times the volume of the packing material tested. A wet biofilm density of 1.11 g mL<sup>-1</sup> was  
237        used to calculate  $\varepsilon_B^{Bed}$ . Finally, the wet biomass was dried for 12 hours at 50 °C to  
238        determine the dry weight of the biomass ( $W_5$ ). The volume fraction occupied by the gas  
239        ( $\varepsilon_G^{Bed}$ ) in the packed bed was also determined taking into account the space occupied by  
240        the abovementioned fractions of the packed bed, including the empty bed fraction of the  
241        packing material reported by the manufacturer (352 m<sup>2</sup> m<sup>-3</sup>).

242        The fraction of biomass in the biofilm ( $\varepsilon_x$ ) was also determined. It was obtained by  
243        analyzing the concentration of total nitrogen in the washed and centrifuged biofilm. The  
244        general formula C<sub>5</sub>H<sub>7</sub>NO<sub>2</sub> typically used to represent the composition of biomass [44]  
245        was used to convert the concentration of total nitrogen into biomass concentration. Then,  
246        the biomass concentration was divided by the total solids concentration (considered as  
247        biofilm concentration) to obtain the biomass fraction in the biofilm. Total solids were  
248        analyzed following the standard method for wastewater analysis [45]. Total nitrogen was  
249        analyzed spectrophotometrically (DR3900, Hach, Spain) using cuvette tests (LCK238,  
250        Hach, Spain).

251

### 252 3. MATHEMATICAL MODEL DEVELOPMENT

253 A three-phase model taking into account the mass balances in the gas and liquid phases  
254 and within the biofilm was developed to describe the dynamics in the heterogeneous  
255 respirometer considering gas and liquid phase recirculation under counter-current flow  
256 pattern. The model includes mathematical expressions for the description of mass  
257 transport by advection in both the gas and the liquid phase, mass transfer through the gas-  
258 liquid interface, mass transfer at the liquid-biofilm interface, internal mass transport in  
259 the biofilm and microbial kinetics within the biofilm. The main assumptions, mass  
260 balances and model equations considered in this work to describe H<sub>2</sub>S oxidation in the  
261 heterogeneous respirometer can be found in the Supplementary Information (section  
262 S1.1).

#### 263 3.1. Modeling mass transfer and mass transport phenomena

264 Gas-liquid and liquid-biofilm mass transport mechanisms were described using global  
265 mass transfer coefficients referred to the liquid phase ( $K_L$ ) and the biofilm ( $K_B$ ),  
266 respectively, while mass transport within the biofilm was modeled by diffusion according  
267 to Fick's Law using a dispersion coefficient ( $D_B$ ).

268 Mass transport coefficients were determined using empirical correlations as a function  
269 of the operating conditions.  $K_L$  for both H<sub>2</sub>S and O<sub>2</sub> were determined using the Billet and  
270 Schultes correlation [46] (Eq. 1), based on the good agreement with experimental  
271 determination on previous modeling studies under similar operating conditions [2,47].

$$K_{L,i} = C_L \cdot \left( \frac{\rho_L \cdot g}{\mu_L} \right)^{1/6} \cdot \left( \frac{D_{L,i}}{d_h} \right)^{1/2} \cdot \left( \frac{u_L}{a_p} \right)^{1/3} \quad (1)$$

272 Where  $K_{L,i}$  is the global mass transfer coefficient for component  $i$  (m h<sup>-1</sup>),  $C_L$  is the  
273 packing material-specific constant,  $\rho_L$  is the liquid density (kg m<sup>-3</sup>);  $g$  is the gravitational  
274 constant (m s<sup>-2</sup>),  $\mu_L$  is the liquid viscosity (kg m<sup>-1</sup> s<sup>-1</sup>),  $D_{L,i}$  is the diffusion coefficient in  
275 the liquid of species  $i$  (m<sup>2</sup> s<sup>-1</sup>),  $d_h$  is the hydraulic diameter of packing material defined by  
276  $4\epsilon/a_p$  (m),  $u_L$  is the superficial liquid velocity (m s<sup>-1</sup>) and  $a_p$  is the packing material specific  
277 surface area (m<sup>-1</sup>).

278 According to Guimerà et al. [6] the effect of hydrodynamic conditions and biofilm  
279 density in the calculation of both external ( $K_B$ ) and internal ( $D_B$ ) mass transport  
280 coefficients were included by using Eq. 2 and Eq. 3, respectively.

$$\text{Sh}_i = 0.238 \cdot \text{Re}^{0.8} \cdot \text{Sc}_i^{0.33} \quad (2)$$

$$D_{r,i} = 0.93 - 0.023 \cdot X_b + 1.2 \cdot 10^{-2} \cdot \text{Re}^2 + 1.1 \cdot 10^{-4} \cdot X_b^2 \quad (3)$$

281 Where  $\text{Sh}_i$  is the Sherwood number for species  $i$  defined by  $K_{B,i}/(D_{L,i}/L_c)$ ,  $L_c$  is the  
282 boundary layer thickness (m),  $\text{Re}$  is the Reynolds number defined by  $(\rho_L \cdot u_L \cdot d_h)/\mu_L$ ,  $\text{Sc}_i$  is  
283 the Schmidt number for species  $i$  defined by  $\mu_L/(\rho_L \cdot D_{L,i})$ ,  $D_{r,i}$  is the relative dispersion  
284 coefficient within the biofilm defined by  $D_{B,i}/D_{L,i}$ , and  $X_b$  is the biofilm density (g VSS L<sup>-1</sup>).  
285

### 286 **3.2. Modeling biological and chemical oxidation of sulfur compounds**

287 The biological degradation of H<sub>2</sub>S within the biofilm was described through a previous  
288 model developed after the characterization of the same H<sub>2</sub>S-oxidizing biofilm used in this  
289 study [3]. The kinetic model considers that sulfide is partially oxidized to elemental  
290 sulfur, which is intracellularly stored by bacteria. Elemental sulfur is partially oxidized to  
291 sulfite that, in the presence of sulfide, reacts to form thiosulfate. Once sulfide is  
292 completely depleted, elemental sulfur and thiosulfate are oxidized to sulfate, the end  
293 product of the biological reactions. Detailed information about the bioprocess  
294 stoichiometry and kinetics considered in this study can be found in the Supplementary  
295 Information (section S1.3, Fig. S1, and Tables S1 and S2).

### 296 **3.3. Model implementation: system discretization and parameters estimation**

297 The resolution of the dynamic mass balance equations (Eqs. S1 to S5 in the  
298 Supplementary Information) that describe the biological, physical and chemical  
299 phenomena taking place in the heterogeneous respirometer was performed by a  
300 discretization procedure. In this study, the 2D model of the trickled bed was spatially  
301 discretized, resulting in 4 nodes along the height of the bed and 6 nodes along the depth  
302 of the biofilm. Detailed information about the resulting equations from the discretization  
303 can be found in the Supplementary Information (S1.5).

304 A sensitivity analysis was performed before the model calibration to determine the  
305 influence of selected model parameters variation ( $\pm 10\%$ ) on the relative change of DO

306 concentration in the liquid phase as model output. Parameters showing higher sensitivities  
 307 were estimated by fitting the simulated DO concentration profiles to the experimental  
 308 profiles. The fitting method was based on seeking the minimum value of the objective  
 309 function. This function was defined as the norm of the differences between the predicted  
 310 DO concentrations by the mathematical model and the experimental data (Eq. 4), both in  
 311 the liquid phase and within the biofilm.

$$F_j = \sqrt{\sum_{i=1}^n [y_{\text{exp}(ij)} - y_{\theta(ij)}]^2} \quad (4)$$

312 where  $F_j$  is the normalized difference between simulated and experimental DO  
 313 concentrations at the phase  $j$ ,  $n$  is the number of experimental measurements,  $y_{\theta(i,j)}$  is the  
 314 simulated DO concentration ( $\text{mg L}^{-1}$ ) at the phase  $j$  and instant  $i$  and  $y_{\text{exp}(i,j)}$  is the  
 315 experimental DO concentration ( $\text{mg L}^{-1}$ ) at the phase  $j$  and instant  $i$ . Considering that DO  
 316 consumption was not observed in the deeper biofilm layers, the phases  $j$  were defined as  
 317 liquid recirculation DO concentration and the DO concentration measured in the first 4  
 318 layers of biofilm. The  $F$  function was calculated as the unweighted sum of  $F_j$ . Parameters  
 319 estimation was performed using the MATLAB algorithm based on a multidimensional  
 320 unconstrained nonlinear minimization (Nedler-Mead).

321

## 322 **4. RESULTS AND DISCUSSION**

### 323 **4.1. Assessment of model parameters**

324 Parameters of the mathematical model were classified as follows [2]: physical-  
 325 chemical properties, mass transport and biokinetic parameters and system specifications.  
 326 In the present study, physical and chemical parameters were obtained from the literature  
 327 [48,49]. Mass transport parameters were calculated using Eqs. 1-3, while kinetic and  
 328 stoichiometric parameters were obtained from Mora et al. [3]. A summary of the physical-  
 329 chemical properties and biokinetic parameters used in this work are found in the  
 330 Supplementary Information (Table S3).

331 Parameters related to system specifications were determined experimentally (Table 1).  
 332 The packing material used herein showed a liquid retention capacity ( $\varepsilon_L^{\text{Bed}}$ ) of  $0.06 \text{ m}^3$   
 333 liquid  $\text{m}^{-3}$  of packed bed, which is lower than  $0.09 \text{ m}^3$  liquid  $\text{m}^{-3}$  bed obtained using  
 334 polyurethane foam or  $0.10 \text{ m}^3$  liquid  $\text{m}^{-3}$  bed using 10 mm pall rings [28]. Moreover, the

335 packed bed exhibited a higher bed void fraction ( $0.8 \text{ m}^3 \text{ gas m}^{-3} \text{ bed}$ ) compared to that  
336 obtained by [28] ( $0.7 \text{ m}^3 \text{ gas m}^{-3} \text{ bed}$ ). The liquid fraction in the packed bed ( $\varepsilon_L^{Bed}$ ) is  
337 important since it is strongly related to the mass transfer rate. High static hold-ups are  
338 found when the liquid is loosely retained inside stagnant regions. The latter diminishes  
339 the specific area available for G-L contact and increases the mass transport resistance  
340 through molecular diffusion between the liquid and biofilm phases [50]. Thus, a high  
341 static hold-up decreases the G-L mass transfer rate in trickled beds. Result obtained herein  
342 indicated the existence of efficient distribution of the liquid film in the packed bed given  
343 that the static hold-up was 25% lower than the dynamic hold-up. Trejo-Aguilar et al. [50]  
344 also reported a positive influence of the liquid fraction on the pollutant elimination  
345 capacity at a packed bed void fraction of  $0.8 \text{ m}^3 \text{ gas m}^{-3} \text{ bed}$  associated with a higher  
346 wetting efficiency in the packed bed. Although the packing material used in this study  
347 had a lower superficial area than the 10 mm Pall ring used in Bonilla-Blancas et al. [28]  
348 ( $a_p$  of  $482 \text{ m}^2 \text{ m}^{-3}$ ), a similar biofilm fraction was determined ( $\varepsilon_B^{Bed}$  of  $0.063 \text{ m}^3 \text{ biofilm}$   
349  $\text{m}^{-3} \text{ bed}$  compared to  $0.06 \text{ m}^3 \text{ biofilm m}^{-3} \text{ bed}$ ). This result, together with the  $\varepsilon_L^{Bed}$  and the  
350 dynamic hold-up obtained for the packed bed used herein, pointed to a proper and optimal  
351 biofilm distribution throughout the packing material.

#### 352 **4.2. Analysis of the respirometric tests performed in the heterogeneous** 353 **respirometer**

354 Experimental tests performed in the heterogeneous respirometer to study  $\text{H}_2\text{S}$   
355 biological oxidation consisted of spiking the gas phase with a specific volume of  $\text{H}_2\text{S}$   
356 ( $200 \mu\text{L}$ ,  $1 \text{ mL}$ ,  $5 \text{ mL}$  and  $10 \text{ mL}$ ), which corresponded to initial gas phase concentrations  
357 ranging from 135 to 6720 ppm<sub>v</sub>. In Fig. 2a, the overall respirogram recorded is presented.  
358 Figures 2b and 2c show specifically the DO and  $\text{O}_2$  profiles for the 5 mL  $\text{H}_2\text{S}$  pulse.

359 During the first part of the experiment ( $t < 1.3 \text{ h}$ ), the endogenous activity was evaluated  
360 from the slope of the oxygen concentration and the DO concentration in the gas and liquid  
361 phases (Fig. 2a), respectively. The DO concentration profile presented a sharp negative  
362 slope indicating that elemental sulfur was still accumulated within the packed bed, and  
363 that the endogenous phase was not achieved with the initial starvation period. An initial  
364 elemental sulfur concentration within the biofilm of  $3.5 \text{ g S m}^{-3}$  was determined through  
365 mass balance from the monitoring data of the BTF from where the colonized packing

366 material was extracted, and later incorporated into the model as initial conditions used to  
367 simulate the respirometric tests.

368 Each H<sub>2</sub>S pulse (Fig. 2a) was added to the system and the response from both the liquid  
369 and gas phases was assessed. Fig. 2a shows that the DO concentration monitoring in the  
370 bulk liquid phase has a much higher sensitivity than that of O<sub>2</sub> concentration in the bulk  
371 gas phase. The addition of H<sub>2</sub>S in the gas phase caused high variations in the DO profile  
372 due to the H<sub>2</sub>S-oxidizing activity, which indicated that the rate-controlling step was  
373 apparently the oxygen transfer from the gas to the liquid phase.

374 The DO concentration in the biofilm was monitored throughout respirometric tests  
375 using the DO microsensor. Results obtained from DO monitoring within the biofilm for  
376 pulses from 135 to 6720 ppm<sub>v</sub> of H<sub>2</sub>S in the gas phase are shown in detail in  
377 Supplementary Information (section S1.6). In these results, DO concentration is only  
378 presented for 6 biofilm layers despite 8 biofilm depths were monitored since DO  
379 concentrations were below the detection limit (L<sub>D</sub> of 0.05 mg O<sub>2</sub> L<sup>-1</sup>) in deeper biofilm  
380 layers. Below 600 μm of biofilm depth, the measured concentration was lower than the  
381 L<sub>D</sub> of the sensor indicating that anaerobic conditions were reached at these depths.  
382 Therefore, results obtained from the deepest biofilm layers were excluded from the  
383 modelling study.

384 Sulfate and thiosulfate were also analyzed before and after the addition of each H<sub>2</sub>S  
385 pulse in the respirometer. The most significant results were observed for the 5 mL (Fig.  
386 2b and 2c) and 10 mL H<sub>2</sub>S pulses, where only sulfate was detected. In the first case  
387 (addition of 5 mL), 6.55 mg S-H<sub>2</sub>S were added and 6.50 mg S-Sulfate were recovered.  
388 This result indicates that sulfide was oxidized completely to sulfate without producing  
389 any other sulfur compound. In the second case (10 mL), 13.1 mg S-H<sub>2</sub>S were added while  
390 only 9.68 mg S-Sulfate were recovered as sulfate, thus indicating that elemental sulfur  
391 was produced and that the maximum sulfide oxidation capacity was already reached  
392 under those conditions.

393 The DO experimental profiles (both in the liquid phase and within the biofilm)  
394 recorded during the endogenous period were used to estimate: the depth of the first  
395 biofilm layer ( $z_{ini}$ ), the packing material constant used in Eq. 1 ( $C_L$ ) and the decay rate  
396 ( $b_H$ ). These parameters were selected based on the high sensitivity of model outputs to  
397 the variation of these three parameters (Table S4). The fitting of the mathematical model

398 to the experimental profiles (Figure S3) allowed estimating a  $z_{ini}$  of  $3.069 \cdot 10^{-5}$  m, a  $C_L$  of  
399 0.2175 and a  $b_H$  of  $8.96 \cdot 10^{-6}$  g O<sub>2</sub> g TS<sup>-1</sup> s<sup>-1</sup>.

#### 400 **4.3. H<sub>2</sub>S oxidation modeling in the trickled bed considering biofilm as a** 401 **homogeneous layer**

402 As the first approach towards the simulation of H<sub>2</sub>S biodegradation in the  
403 heterogeneous respirometer, a homogeneous biofilm (both constant density and  
404 biological activity) was considered. This is the most common approach in biofiltration  
405 using 2D biofilm modeling. Biokinetic parameters, characteristic of the biomass used in  
406 this study, were previously characterized in Mora et al. [3]. However, they also reported  
407 that kinetic constant describing elemental sulfur oxidation ( $k_S$ ) (Table S2) depends on the  
408 type of sulfur and the sulfur particle shape produced by the specific H<sub>2</sub>S-oxidizing  
409 bacteria developed in each experimental system. In Mora et al. [3]  $k_S$  was estimated as a  
410 range instead of as a parameter. For this reason, experimental DO profiles corresponding  
411 to period IV were used to estimate  $k_S$  value. Finally, the estimated value of biokinetic  
412 parameter during model calibration was  $0.103 \text{ g S}^{1/3} \cdot \text{g}^{-1/3} \text{ VSS}$ . In Fig. 3, experimental  
413 and simulated respirometric profiles corresponding to the 5 mL pulse of H<sub>2</sub>S are  
414 presented. Results obtained showed minimal differences in the evolution of measured  
415 oxygen concentration in the gas phase. This trend was expected since biofilm dynamics  
416 slightly influence gas-liquid mass transport phenomena of poorly soluble compounds as  
417 O<sub>2</sub>. Regarding the liquid phase, experimental and simulated DO profiles also showed  
418 minor differences, although the predicted DO concentration decay was slightly lower than  
419 the experimental one resulting in a higher simulated DO concentration at the steady-state  
420 (after 450 s). Within the biofilm, higher differences between experimental and simulated  
421 DO profiles were found. Predicted DO profiles presented a high DO decrease as a result  
422 of H<sub>2</sub>S consumption. As can be observed in Fig. 3b, DO concentration in the more  
423 superficial (i.e. first) biofilm layer fell below 1 mg L<sup>-1</sup>, while experimental DO  
424 concentration remained above 3.5 mg L<sup>-1</sup>. Deviations between experimental and  
425 simulated profiles decreased for the first three biofilm layers from the surface after 500 s  
426 of monitoring, when H<sub>2</sub>S was depleted. On the other hand, unlike experimental results,  
427 anaerobic conditions were predicted below 400 μm of biofilm throughout the monitored  
428 period.

429 The comparison between experimental and simulated profiles confirmed that  
430 considering a homogeneous structure of biofilm is not adequate for biofilm modeling.

431 Thus, a realistic description of functional and structural characteristics of biofilm is  
432 required in order to accurately predict biofilm dynamics.

#### 433 **4.4. H<sub>2</sub>S oxidation modeling in the trickled bed considering biofilm as a** 434 **heterogeneous layer**

435 The mathematical model describing biological H<sub>2</sub>S oxidation in the heterogeneous  
436 respirometer was improved considering heterogeneous functional and structural  
437 characteristics, such as the biomass density and its active fraction, throughout the biofilm.  
438 Biofilm modeling including heterogeneous characteristics was performed using the same  
439 model parameters presented both in Table 1 and Table S3.

##### 440 **4.4.1. Heterogeneous biofilm description**

441 Biofilm attached to the packing material was described as a heterogeneous phase  
442 considering that some of its properties vary along with its depth. Experimental  
443 determinations obtained in previous works highlighted that inner biofilm layers presented  
444 a higher cell density but a lower biomass activity [36]. According to these results, a  
445 variable biofilm density and active fraction of biomass along the biofilm were included  
446 in the model in order to improve the biofilm description. An exponential distribution was  
447 considered for both parameters following Eq. 5 and Eq. 6.

$$X_b = \rho_b \cdot e^{c_x \cdot z} \quad (5)$$

$$f_a = e^{-c_a \cdot z} \quad (6)$$

448 where  $X_b$  is the biomass concentration within the biofilm (g VSS L<sup>-1</sup>);  $\rho_b$  is the pre-  
449 exponential coefficient for the distribution function of biomass concentration within the  
450 biofilm (g VSS L<sup>-1</sup>);  $C_x$  is the exponential coefficient for the distribution function of  
451 biomass concentration within the biofilm (m<sup>-1</sup>);  $Z$  is the biofilm depth (m);  $f_a$  is the active  
452 fraction of biomass within the biofilm; and  $C_a$  is the exponential coefficient for the  
453 distribution function for the active fraction of biomass within biofilm (m<sup>-1</sup>). The equation  
454 used to define the distribution of biomass concentration within the biofilm (Eq. 5) was  
455 developed using an experimental constraint in order to ensure a reliable biofilm  
456 description. To this aim, the average biofilm density calculated using Eq. 5 must coincide  
457 with the value obtained experimentally following the procedure described in section 2.4.

458 The heterogeneous modeling approach was implemented by replacing  $X_b$  by Eq. 5 in  
459 the kinetic equations (Table S2) and by multiplying the kinetic expressions by the active

460 fraction as described in Eq. 6. The model calibration stage was modified in order to  
461 include the estimation of novel parameters (biomass density and active fraction) defined  
462 in Eq. 5 and Eq. 6. A sensitivity analysis before model calibration was required in order  
463 to assess the influence of mathematical model modifications on its response. The  
464 biokinetic parameters characterized in Mora et al. [3] were used again for heterogeneous  
465 approach simulation. Considering the influence of H<sub>2</sub>S-oxidizing bacteria on elemental  
466 sulfur oxidation, the  $k_S$  was also included in the calibration step to describe more  
467 accurately the biokinetics of the biofilm.

#### 468 **4.4.2. Sensitivity analysis for parameters estimation**

469 Model sensitivity to  $C_x$ ,  $C_a$  and  $k_s$  was assessed for the 5 mL pulse of H<sub>2</sub>S. The values  
470 of  $C_x$  and  $C_a$  resulting in an homogeneous biofilm description and the reference value of  
471  $k_S$  obtained from Mora et al. [3] were used to perform the sensitivity analysis. Results  
472 obtained from the sensitivity analysis are shown in Table 2.

473 The DO concentration in the liquid phase and within biofilm exhibited a remarkable  
474 sensitivity to all parameters tested. The most sensitive parameter was the kinetic constant  
475 for elemental sulfur oxidation ( $k_S$ ), since DO concentration is highly dependent on  
476 consumption rates. These results indicated that elemental sulfur production and  
477 accumulation plays a major role as an intermediate compound and should be included and  
478 described adequately through the kinetic model. Sulfide oxidation rate can be diminished  
479 by excessive elemental sulfur accumulation, which is directly influenced by the rate  
480 during which elemental sulfur is consumed ( $k_S$ ). On the other hand, parameters related to  
481 density and activity distribution within biofilm also showed an influence on the output  
482 variable. The high sensitivity values obtained for the parameters associated with the  
483 description of the biofilm heterogeneity, highlights the importance of the incorporation  
484 of this assumption into the mathematical model. Since the other parameters are either  
485 known experimentally or bibliographically referenced, the three parameters proposed for  
486 model calibration were the parameters related to the characterization of the biofilm  
487 heterogeneity ( $C_x, C_a, k_s$ ).

#### 488 **4.4.3. Model calibration**

489 The mathematical model was calibrated using the experimental data from period IV,  
490 corresponding to a substrate pulse of 5 mL. The estimated parameters during the  
491 calibration step are shown in Table 3. Discussion about  $C_x$  and  $C_a$  values with respect to

492 literature could not be performed since this is the first time that these parameters have  
493 been included in biofilm modeling to describe heterogeneous structure and activity. In  
494 this sense, a discussion about biofilm density and activity distribution calculated from  
495 calibration results is presented in section 4.4.4. The estimated value for  $k_s$  lied within the  
496 typical range reported in the literature that is between 0.833 and 0.030  $\text{g S}^{1/3} \text{g}^{-1/3} \text{VSS}$ .

497 In Fig. 4, the predicted and experimental oxygen profiles in the gas, liquid and biofilm  
498 phases after model calibration are shown. The agreement between experimental DO  
499 concentration profiles and model estimations was evaluated through the normalized root  
500 mean square error (NRMSE). The NRMSE calculated for DO concentration profiles in  
501 gas and liquid phases, and within biofilm are presented in Table 4. Simulated oxygen  
502 profiles in liquid and gas phases predicted accurately (NRMSE<10%) the experimentally  
503 observed trends (Fig. 4a). Differences between experimental and simulated oxygen  
504 evolution in the gas phase were smaller, considering a heterogeneous biofilm (Fig. 4a)  
505 than considering a homogeneous biofilm (Fig. 3a). In the same way, heterogeneous  
506 biofilm modeling also allowed an accurate simulation of the DO concentration in the  
507 liquid phase. Although slight differences could be observed in the initial slope, a similar  
508 DO concentration profile was predicted during  $\text{H}_2\text{S}$  consumption (between 100 and 450  
509 s) and at the steady-state (after 450 s). The model also described satisfactorily the  
510 experimental oxygen distribution within the biofilm for DO concentrations above the DO  
511 detection limit of the microsensors ( $0.05 \text{ mg DO L}^{-1}$ ). Thus, the mathematical model  
512 developed in this work provided a better simulation of DO distribution within the biofilm,  
513 under  $\text{H}_2\text{S}$  oxidation conditions, compared with modeling the biofilm as a homogeneous  
514 layer. These results highlighted that the addition of a heterogeneous biofilm description  
515 in trickled beds modeling, such as that found in a BTF or in the heterogeneous  
516 respirometer, improves biological activity description as well as the description of gas  
517 and liquid phase dynamics.

#### 518 **4.4.4. Prediction of selected model variables**

519  $\text{H}_2\text{S}$ , sulfate and elemental sulfur concentrations were also model variables not  
520 monitored on-line but estimated by the model.  $\text{H}_2\text{S}$  and sulfate concentration evolution in  
521 the liquid phase and within the biofilm are shown in Fig. 5. Elemental sulfur concentration  
522 within the biofilm is presented in Fig. 6a. Complementarily, biofilm density and activity  
523 distribution are shown in Fig. 6b.

524 Simulated H<sub>2</sub>S profiles showed that 3360 ppm<sub>v</sub> of H<sub>2</sub>S were depleted both in the gas  
525 and in the liquid phase 200 s after its injection (Fig. 5a). The H<sub>2</sub>S within the first biofilm  
526 layer was also consumed during the first 200 s and kept close to zero for the inner layers  
527 during all the simulated period (Fig. 5b). The evolution of simulated H<sub>2</sub>S concentration  
528 proved a low mass transport resistance at the liquid-biofilm interface. Therefore, it can be  
529 concluded that the biological oxidation capacity of the system was only limited by oxygen  
530 liquid-biofilm mass transport rate. This is confirmed by elemental sulfur production  
531 during H<sub>2</sub>S biological oxidation. Elemental sulfur was produced as an intermediate during  
532 H<sub>2</sub>S oxidation and was totally consumed before 200 s, except in the inner layers of the  
533 biofilm where limiting-oxygen conditions caused the accumulation of a small amount of  
534 sulfur until practically the end of the simulated period. In this sense, until 600 and 800 s,  
535 elemental sulfur was not totally depleted at a depth of 500 and 625 μm, respectively.  
536 Considering that sulfate was the final product of the oxidation, the sulfate concentration  
537 profile in the bulk liquid phase (Fig. 5c) exhibited a progressive step-like concentration  
538 increase caused by the oxidation of H<sub>2</sub>S injected in the pulse and the elemental sulfur  
539 generated as intermediate. Sulfate was only produced after 100 s of simulating time when  
540 the elemental sulfur produced as the first oxidation product started to be oxidized (Fig.  
541 6a). Sulfate concentration reached its final concentration at around t=400 s when H<sub>2</sub>S  
542 oxidation was finished and all the elemental sulfur produced was completely oxidized.  
543 Insignificant differences were found between the simulated sulfate concentration (629 mg  
544 S L<sup>-1</sup>) and the measured sulfate concentration in the liquid phase after the initial pulse  
545 (639 mg S L<sup>-1</sup>). As shown in Fig. 5d, high mass transport rates helped to homogenize  
546 sulfate profiles within the biofilm. In this sense, although different sulfate production  
547 rates were obtained at the beginning of the simulated period, until 200 s, the same  
548 concentration was reached in all simulated depths at the steady state (after 400 s).

549 The spatial distribution of biofilm properties was also assessed. The simulation results  
550 presented in Fig. 6b confirmed that the cell density increased in the deeper layers of the  
551 biofilm. Results indicated that the biofilm density increased 14% along with the biofilm  
552 depth, from 3205 at the biofilm surface to 4430 g VSS L<sup>-1</sup> deeper on. This trend is in  
553 agreement with experimental determinations in biofilms systems presented in Zhang and  
554 Bishop [51]. The increase in cell density results in a decrease in the biofilm porosity and,  
555 consequently, in a lower dispersion rate of chemicals within the biofilm. In this case, the  
556 relative dispersion coefficient ( $D_r$ ) from the surface to the inner parts of the biofilm varied

557 between 0.31 and 0.26, respectively. Such 14% decrease in the dispersion coefficient  
558 within the biofilm was consistent with the mass transport rate distribution experimentally  
559 determined [36,52]. In the same way, several works have suggested a stratification in the  
560 biofilm activity, but conventional monitoring tools have not allowed to check and  
561 quantify activity gradients through biofilm layers. Remarkably, monitoring tools  
562 presented herein allowed estimating a distribution of the biological activity through the  
563 biofilm in the trickled bed. The calibration results showed a gradient in the fraction of  
564 active bacteria within the biofilm, which decreased from 0.95 to 0.45 along a biofilm  
565 section (Fig. 6b). These results are in high agreement with results presented in Zhang and  
566 Bishop [46] where a viable bacteria decrease from 91 to 39% was detected. In Mirpuri et  
567 al. [48] a qualitative explanation of the physiological biofilms stratification was proposed  
568 considering three categories of bacteria: those capable of degrading pollutants at high  
569 concentrations, those that can degrade pollutants at a low concentration under favorable  
570 conditions and those that cannot degrade pollutants at all. Experimental determinations  
571 indicated that the pollutants degrader bacteria are abundant near the liquid-biofilm  
572 interface while the other types are abundant deeper in the biofilm.

573

## 574 **5. CONCLUSIONS**

575 Coupling heterogeneous respirometry and DO microsensor specifically designed for  
576 biofilm profiling provided a complete tool for the characterization of biofiltration systems  
577 from a comprehensive monitoring through gas, liquid and biofilm phases. The improved  
578 heterogeneous respirometer exhibited a high performance for the study of multiphase  
579 processes taking place in packed bed systems such as biotrickling filters. Coupling  
580 experimental gas, liquid and biofilm data with a biofiltration model considering biofilm  
581 structural and functional heterogeneity, resulted in a complete characterization of the  
582 system. Mass transport and biokinetic mechanisms description were achieved from  
583 results obtained in the current study. To the best of our knowledge, this is the first work  
584 where a trickled bed is modeled as a 2D stratified system including experimental data  
585 from biofilm profiling. Results obtained allows deepening in the knowledge of biofilm  
586 processes and structure as well as improving the description provided by biofilm models.

587

761

762 **Fig. 1.** (a) Schematic of the heterogeneous respirometer. 1. dissolved oxygen sensor, 2. liquid  
763 recirculation line, 3. liquid recirculation pump, 4. pH sensor, 5. gas out, 6. packed bed container,  
764 7. free gas (gas volume not contained in the packed bed), 8. liquid reservoir, 9. pulse port, 10.  
765 liquid purge, 11. gas in, 12. O<sub>2</sub> sensor, 13. gas recirculation line, 14. gas recirculation compressor,  
766 15. micro-burette for pH control; (b) DO microsensor; (c) detailed image of the biofilm  
767 monitoring port with the DO-MEA installed.

768

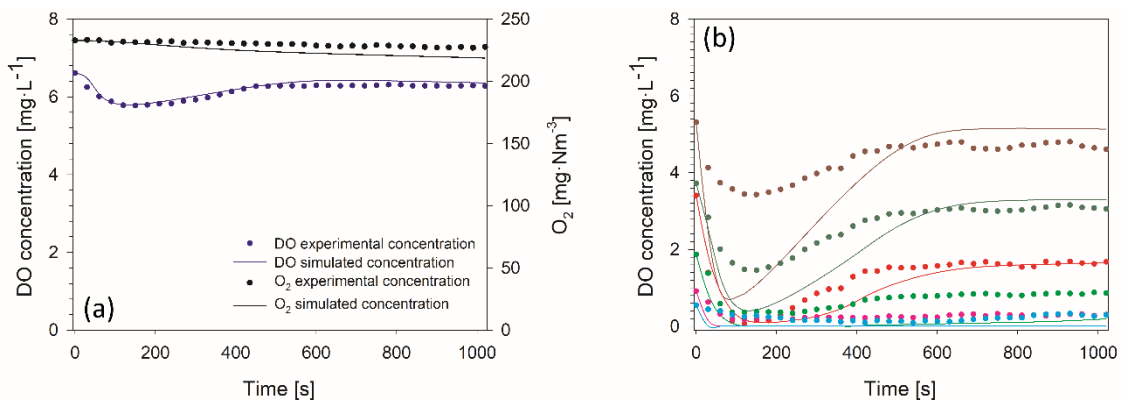

769

770 **Fig. 2.** (a) Respirometric profiles obtained from oxygen monitoring in gas and liquid phases  
 771 during the endogenous stage and during pulses of 200  $\mu\text{L}$  (135 ppm<sub>v</sub>), 1 mL (675 ppm<sub>v</sub>), 5 mL  
 772 (3360 ppm<sub>v</sub>) and 10 mL (6720 ppm<sub>v</sub>) of H<sub>2</sub>S. Vertical lines show the instant of pulses injection.  
 773 Oxygen concentration profile in the liquid phase (b) and gas phase (c) during the oxidation of  
 774 3360 ppm<sub>v</sub> of H<sub>2</sub>S.

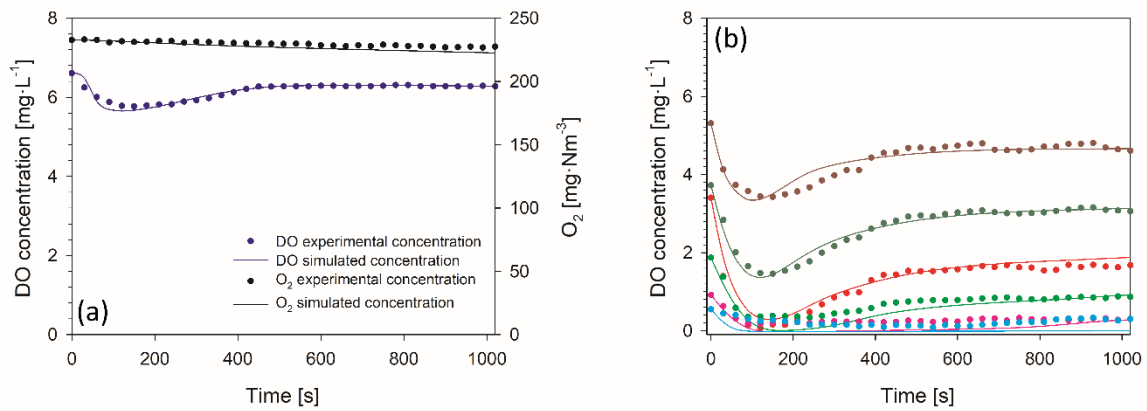

775

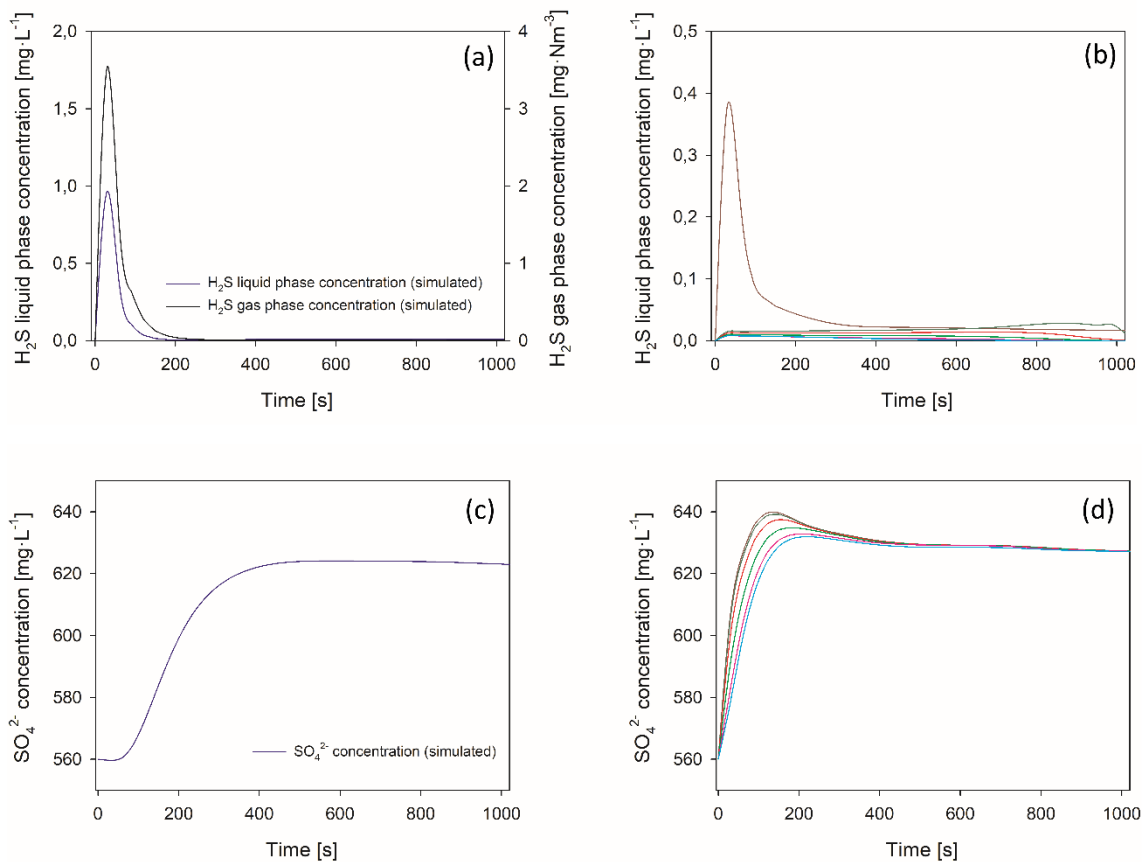

776

777 **Fig. 3.** Experimental (symbols) and simulated (solid lines) oxygen concentration profiles during  
 778 the 5 mL H<sub>2</sub>S pulse considering a homogeneous biofilm (constant density and biomass activity)  
 779 in (a) the liquid and gas phases and (b) within the biofilm. Monitored depths are plotted in

780 different colors: brown (30  $\mu\text{m}$  depth), green (155  $\mu\text{m}$  depth), red (280  $\mu\text{m}$  depth), light green  
 781 (405  $\mu\text{m}$  depth), purple (530  $\mu\text{m}$  depth) and light blue (655  $\mu\text{m}$  depth).  
 782

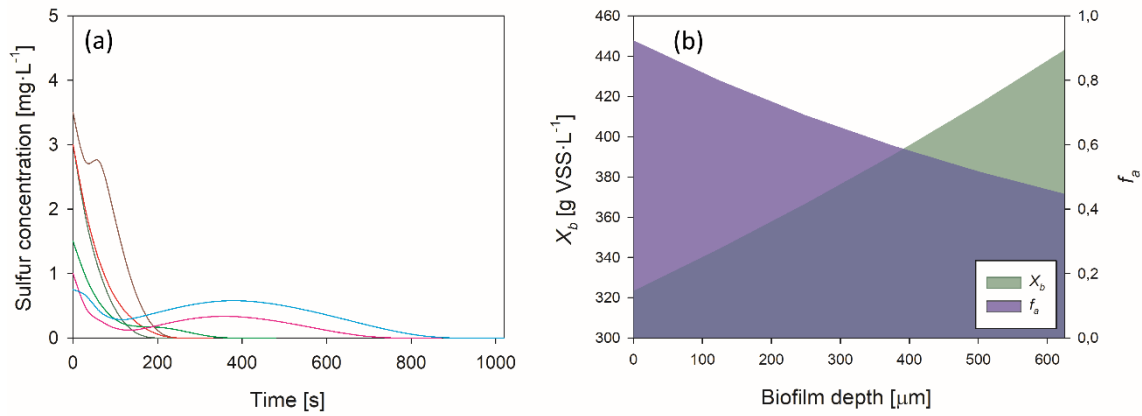

783  
 784 **Fig. 4.** Experimental (symbols) and simulated (solid lines) DO profiles in (a) gas and liquid phases  
 785 and (b) within biofilm, used in model calibration. Profiles correspond to the 5 mL of H<sub>2</sub>S.  
 786 Monitored depths are plotted in different colors: brown (30  $\mu\text{m}$  depth), green (155  $\mu\text{m}$  depth), red  
 787 (280  $\mu\text{m}$  depth), light green (405  $\mu\text{m}$  depth), purple (530  $\mu\text{m}$  depth) and light blue (655  $\mu\text{m}$  depth).  
 788

789  
 790 **Fig. 5.** Simulated H<sub>2</sub>S in the (a) gas and liquid phase and (b) within the biofilm, sulfate  
 791 concentration in the liquid phase (c) and within 6 simulated biofilm depths (d) during a pulse of  
 792 5 mL of H<sub>2</sub>S. Monitored depths are plotted in different colors: brown (30  $\mu\text{m}$  depth), green (155

793  $\mu\text{m}$  depth), red (280  $\mu\text{m}$  depth), light green (405  $\mu\text{m}$  depth), purple (530  $\mu\text{m}$  depth) and light blue  
 794 (655  $\mu\text{m}$  depth).

795

796

797 **Fig. 6.** (a) Simulated elemental sulfur concentration within 6 simulated biofilm depths during a  
 798 pulse of 5 mL of  $\text{H}_2\text{S}$ . Monitored depths are plotted in different colours: brown (30  $\mu\text{m}$  depth),  
 799 green (155  $\mu\text{m}$  depth), red (280  $\mu\text{m}$  depth), light green (405  $\mu\text{m}$  depth), purple (530  $\mu\text{m}$  depth)  
 800 and light blue (655  $\mu\text{m}$  depth). (b) Biofilm density and activity distribution within a biofilm  
 801 section calculated from calibration results (Eq. 4 and Eq. 5).

802

803 **Table 1.** Parameters related to system specifications experimentally determined in the  
 804 heterogeneous respirometer.

Parameter	Value	Units
$V_L$	$1.26 \cdot 10^{-4}$	$\text{m}^3$
$V_G$	$14.9 \cdot 10^{-4}$	$\text{m}^3$
$V_{Bed}$	$6.30 \cdot 10^{-4}$	$\text{m}^3$
Dynamic hold-up	$23.5 \cdot 10^{-6}$	$\text{m}^3$
Static hold-up	$17.7 \cdot 10^{-6}$	$\text{m}^3$
Biofilm amount	16.2	$\text{g TS}^a$
$\epsilon_x$	0.11	$\text{g bacteria g}^{-1} \text{TS}$
$\epsilon_L^{Bed}$	0.065	$\text{m}^3 \text{ liquid m}^{-3} \text{ bed}$
$\epsilon_B^{Bed}$	0.063	$\text{m}^3 \text{ biofilm m}^{-3} \text{ bed}$
$\epsilon_G^{Bed}$	0.762	$\text{m}^3 \text{ gas m}^{-3} \text{ bed}$

$\varepsilon_S^{Bed}$  0.110 m<sup>3</sup> material m<sup>-3</sup> bed

805 <sup>a</sup>Total Solids (TS)  
806

807 **Table 2.** Sensitivity results of DO in the liquid phase and within first biofilm layer to selected model  
808 parameters for the heterogeneous biofilm model assessed for the 5 mL H<sub>2</sub>S pulse.

Parameter	Units	DO liquid phase		DO Biofilm	
		Sensitivity,	Sensitivity,	Sensitivity,	Sensitivity,
		+Δ10%	-Δ10%	+Δ10%	-Δ10%
$C_x$	m <sup>-1</sup>	0.148	0.137	0.358	0.391
$C_a$	m <sup>-1</sup>	0.189	0.168	0.411	0.396
$k_S$	g S <sup>1/3</sup> g <sup>-1/3</sup> VSS	-2.599	-2.794	5.781	3.487

809

810 **Table 3.** Model parameters estimated and calculated from the fitting of the improved  
811 mathematical model to the experimental respirometric profiles.

Parameter	Value	Units
$C_x$	262.28	m <sup>-1</sup>
$C_a$	821.98	m <sup>-1</sup>
$k_S$	0.0731	g S <sup>1/3</sup> g <sup>-1/3</sup> VSS

812

813 **Table 4.** Normalized root mean square errors (NRMSE) between experimental DO concentration  
814 profiles and model simulations in the gas and liquid phase, and within biofilm.

DO concentration profile	NRMSE [%]	
Gas phase	1.4	
Liquid phase	1.1	
Biofilm	30 μm	3.5
	155 μm	2.4
	280 μm	3.2
	405 μm	7.5

815

	530 $\mu\text{m}$	9.3
	655 $\mu\text{m}$	11.1
