Abstract. The fracture resistance of different advanced high strength steel (AHSS) sheets for automotive applications is investigated through conventional tensile tests, fracture toughness measurements and hole expansion tests. Different fracture-related parameters, such as the true fracture strain (*TFS*), the true thickness strain (*TTS*), the fracture toughness at crack initiation (w_e^i), the specific essential work of fracture (w_e) and the hole expansion ratio (HER) are assessed. The specific essential work of fracture (w_e) is shown to be a suitable parameter to evaluate the local formability and fracture resistance of AHSS. The results reveal that fracture toughness cannot be estimated from any of the parameters derived from tensile tests and show the importance of microstructural features on crack propagation resistance. Based on the relation fracture toughness-local formability, a new AHSS classification mapping accounting for global formability and cracking resistance is proposed. Furthermore, a physically motivated fracture criterion for edge-cracking prediction, based on thickness strain measurements in fatigue pre-cracked DENT specimens, is proposed.

Keywords: Fracture toughness, advanced high strength steel sheets, stretch flangeability, cracking resistance, local formability

1. Introduction

Advanced high strength steels (AHSS) play a fundamental role in the development of modern lightweight automobiles. The use of these steels for structural and safety related automotive components is undergoing a continuous increase in the last years. The body structure of current passenger cars can have up to 51% of AHSS [1] and this percentage might grow up to 65% in upcoming vehicles [1,2]. The main advantage of AHSS is their excellent combination of high strength and good ductility, which has significantly contributed to reduce the total vehicle mass, while improving crash performance.

The AHSS family comprises a wide variety of complex multiphase microstructures that provide unique combinations of mechanical properties by adjusting their chemical composition and thermomechanical processing routes. AHSS are categorized in three main groups or families: 1st, 2nd and 3rd generation AHSS [1]. Dual Phase (DP), Complex Phase (CP), Martensitic (MS), Press-hardened (PHS) and Transformation-Induced Plasticity (TRIP) steels are part of the 1st generation of AHSS. This generation is characterized by showing higher strength and formability than single-phase high strength low alloyed (HSLA) steels [3]. The 2nd generation includes Twinning-Induced Plasticity (TWIP) and austenitic steels. These steels present excellent ductility compared to the 1st generation AHSS at similar strength levels. However, their high alloy content, which significantly increases production costs, and other problems related to delayed fractures and poor weldability have limited their application [4]. The 3rd generation arose to cover the gap between the 1st and the 2nd generation of AHSS. These steels exhibit higher strength and formability than the 1st generation of steels at significantly lower costs than the 2nd

generation of steels [1]. Some of the steels developed under this classification are TBF (TRIP-aided bainitic ferritic) and Q&P (quenching and partitioning) steels. Other TRIP-assisted steels, such as medium-Mn [5] or δ -TRIP steels [6], and nanoprecipitation steels [7] are under development.

The development of new AHSS with higher strengths has introduced new forming challenges and fracture problems related to their limited cracking resistance, as for example edge fractures, limited hole expandability, etc. [8-10]. Often, these fractures are not coherent with conventional formability criteria based on elongation values from tensile tests or forming limit curves (FLC) [8]. A clear example is the edge formability of DP and CP steels. DP steels usually show lower edge formability and hole expansion ability than CP steels, even though the former have greater uniform and total elongation and higher limit strains in the FLC [9, 11-15]. This inconsistency between fracture resistance and traditional ductility definitions, motivated the development of new formability criteria for AHSS, differentiating between global and local formability [16, 17]. The term global formability refers to the most traditional interpretation of formability, i.e. the resistance against the onset of necking instability, and it is well described by tensile properties (strain hardening exponent, true uniform strain) and FLC. On the other hand, local formability is linked to the material's damage tolerance and cracking resistance (bendability, edge cracking, hole expansion, etc.) and, as mentioned before, has no apparent relation with tensile strength/ductility properties. Consequently, alternative approaches have been developed to experimentally assess the local formability of AHSS. The Hole Expansion Test (HET) according to ISO 16630 [18] is well established as a standard procedure for stretch flangeability evaluation of AHSS sheets and the Hole Expansion Ratio (*HER*) has become an almost mandatory parameter for AHSS products manufacturers. Nevertheless, the *HER* is not a material property and depends on many external factors that can cause large data scattering and compromise its reliability: hole preparation method, edge quality, tool stiffness, test operator, crack detection method, etc. [11,15, 19-24]. In order to overcome such uncertainties and improve the accuracy of edge formability prediction, a series of alternative tests based on optical strain measurements and digital image correlation (DIC) techniques have been proposed [15, 24-29].

More recently, other authors have suggested the use of local fracture strain measurements from uniaxial tensile specimens, such as the true fracture strain (*TFS* or ϵ_f) [16], the reduction of area (*Z*-value) [30] or the true thickness strain (*TTS*) [17,30], as an indicator of local formability of AHSS. Hance [16] proposed the *TFS* derived from the reduction of area fracture surface to assess the fracture resistance of AHSS sheets and, on the basis of this parameter, developed enhanced formability mappings and defined different performance levels for AHSS [16,31]. Larour et al. [30] and Heibel et al. [17] observed a very good correlation between the *TTS* and the *HER* of several AHSS grades. Following the idea of Hance, Heibel et al. proposed a new classification of AHSS according to their global and local ductility, using the true uniform strain and the *TTS*, respectively [17].

By definition, local formability is related to the material's crack nucleation and propagation resistance, i.e. its fracture toughness. Accordingly, other researchers have used different approaches based on fracture mechanics testing for fracture resistance and local ductility assessment of AHSS [9,14,15, 32-35]. For instance, Takahashi et al. [32] investigated stretch flangeability of different hot rolled high strength steels and found a linear correlation between *J_c* and *HER*. Similar correlation between fracture toughness values and *HER* were observed by Casellas et al. [14], Yoon et al. [33] and Frómeta et al. [9, 15]. In [34] and [35], a link was established between crack propagation resistance and crash folding behavior and other local ductility parameters for several AHSS grades (V-bending, local fracture strain from DIC, etc.).

Following such research, the present work aims at providing further evidence on the relationship between fracture toughness and cracking resistance of AHSS and proposes a new fracture performance classification for AHSS according to their crack propagation resistance. The fracture resistance of

different 1st and 3rd generation AHSS steel grades with ultimate tensile strengths (UTS) from 780 to 1180 MPa is investigated by means of uniaxial tensile tests, essential work of fracture tests and hole expansion tests. The correlation between the different parameters is investigated and the role of the main microstructural characteristics on fracture performance is discussed. The microstructure – material performance relationship is addressed by using the fracture toughness and fracture strain values derived from these tests, because such properties are well correlated to edge cracking and impact crack propagation behavior [9,14,15,34,35]. Based on such analysis, a global ductility vs. fracture toughness diagram is presented to describe the overall formability and fracture resistance of AHSS.

2. Materials and methods

2.1. Materials

Six cold rolled AHSS grades in the range of 780-1180 MPa UTS are investigated. The steels were manufactured and supplied by voestalpine Stahl and ArcelorMittal. Table 1 classifies the 6 AHSS grades according to their strength level and AHSS generation. The steel supplier is also indicated. All the steels were provided in the form of 1.4-1.6 mm thick sheets, except for the 3rd Gen DP1180 ($t=1.2$ mm). Microstructures are shown in Figure 1 to Figure 3. The figures show optical micrographs after LePera etching and scanning electron microscope (SEM) images. The chemical compositions and the microstructural constituents are given in Table 2 and Table 3, respectively. The retained austenite (RA) volume fraction was measured via the saturation magnetization method, as explained in [36].

780 MPa grades show a matrix mainly consisting of ferrite (F) and bainite (B) with different amounts of martensite (M) and martensite/retained austenite (M/RA) islands. DP780 has a lower amount of RA when compared to the TRIP780 grade. On the other hand, DP980 has a ferritic-bainitic matrix with some amount of tempered martensite and a lower amount of hard martensite islands, which are finely distributed.

3rd Gen DP1180 both consists of a matrix of partly upper bainite (UB) with globular islands of M/RA, and partly of lower bainite/tempered martensite (LB/TM) with globular and lamellar formed islands of M/RA. The 3rd Gen TBF1180 is composed of a matrix of carbide-free bainite with globular islands of M/RA and laths of RA. However, the structure of the 3rd Gen TBF1180 is a bit coarser than the one of 3rd Gen DP1180, which might be attributed to a larger size in prior austenite grains. The microstructure of the grade 3rd Gen Q&P1180 is significantly different when compared to the 3rd Gen DP1180 and TBF1180 steels. It has a matrix consisting of tempered or carbon-depleted martensite, including lath-like retained austenite, globular islands of M/RA and bainite. All three 1180MPa grades show quite high contents of retained austenite (12-16%).

Table 1. Description of the investigated AHSS grades

AHSS generation	Strength level [MPa]	Steel denomination	Thickness [mm]	Supplier
1 st GEN	780	DP780	1.5	voestalpine
		TRIP780	1.6	ArcelorMittal
	980	DP980	1.35	voestalpine
3 rd GEN	1180	3 rd Gen DP1180	1.2	voestalpine
		3 rd Gen TBF1180	1.4	ArcelorMittal
		3 rd Gen Q&P1180	1.5	ArcelorMittal

2.2. Experimental procedure

2.2.1. Uniaxial tensile tests

Conventional uniaxial tensile tests were performed according to ISO 6892-1 [37]. Standard tensile specimens with a parallel length of 120 mm and a width of 20 mm were machined at transverse orientation respect to the rolling direction. An initial gauge length of 80 mm was used for elongation measurements and 3 specimens per material were tested.

The true fracture strain (TFS), derived from the reduction of area at the fracture location was evaluated according to Equation 1:

$$TFS = \ln\left(\frac{A_0}{A_f}\right) \quad \text{Equation 1}$$

where A_0 is the initial cross section area and A_f is the area at fracture. The area at fracture was measured from the fracture surface of the tensile specimens according to ASTM E8 [38] with an optical microscope. Thickness measurements were performed on the left (t_{left}) and right (t_{right}) edges and in the middle of the fracture surface (t_{mid}) (Figure 4). From this, the thickness at fracture (t_f) was obtained as follows:

$$t_f = \frac{1}{6}(t_{left} + 4t_{mid} + t_{right}) \quad \text{Equation 2}$$

A_f is calculated according to Equation 3:

$$A_f = width_f * t_f \quad \text{Equation 3}$$

where $width_f$ is the width of the fractured area (Figure 4).

The true thickness strain (TTS) was calculated using Equation 4:

$$TTS = \ln\left(\frac{t_0}{t_f}\right) \quad \text{Equation 4}$$

where t_0 is the initial sheet thickness.

Figure 4. Fracture surface of a uniaxial tensile specimen and location of the thickness and width measurements performed to evaluate the TFS and the TTS . The dashed line represents the contour of the fractured area.

2.2.2. Fracture toughness

The fracture toughness of the studied AHSS grades was evaluated by means of the essential work of fracture (EWF) methodology [39]. The method allows to experimentally separate the ductile fracture energy (W_f) into two energetic contributions, as shown in Equation 5.

$$W_f = W_e + W_p = w_e l_0 t_0 + w_p \beta l_0^2 t_0 \quad \text{Equation 5}$$

where W_e is the essential work of fracture developed in the fracture process zone and W_p is the non-essential plastic work dissipated in an outer region surrounding the crack plane. w_e is the specific work of fracture per unit area, l_0 is the ligament length, t_0 is the specimen thickness, w_p is the specific non-essential plastic work per unit volume and β is a shape factor that depends on the shape of the plastic zone. Dividing Equation 5 by the initial cross section area ($l_0 t_0$) gives:

$$\frac{W_f}{l_0 t_0} = w_f = w_e + w_p \beta l_0 \quad \text{Equation 6}$$

According to Equation 6, if a series of specimens with different ligament lengths is tested up to fracture and w_f is plotted against the ligament length (l_0), a straight line is obtained. Then, w_e can be determined by linear extrapolation to zero ligament length. w_e has shown to be a suitable parameter to describe the crack propagation resistance of thin ductile sheets, including polymers [40-42], metals [43-47] and AHSS [9, 14, 15, 34, 35, 48-52]. It is important to point out that the plane stress fracture toughness of thin ductile sheets has an important contribution from necking and, therefore, the measured w_e cannot be considered an intrinsic material property but a material constant for the given sheet thickness.

Even though w_e has shown to be independent of the specimen geometry and can be obtained from different geometries [40, 42], for thin sheets, the EWF testing protocol [53] developed by the European Structural Integrity Society (ESIS) recommends the use of Double Edge Notched Tension (DENT) specimens because of its symmetry and minimal specimen rotation and buckling during testing.

In the present work, EWF tests were performed by testing rectangular DENT specimens with dimensions of 240 x 55 mm machined in the transverse orientation with respect to the rolling direction (notches aligned in the rolling direction). Five different initial ligament lengths (l_0) ranging from 6 to 14 mm were used and 3 specimens per ligament length were tested. The specimens were tested up to fracture at a constant cross-head speed of 1 mm/min. Initial notches were machined by electrical discharge machining (EDM) and fatigue pre-cracks were nucleated at the notch root to avoid the effect of the notch radius on fracture toughness results (Figure 5a).

The fracture toughness at crack initiation (w_e^i) was also assessed by calculating the energy up to the onset of crack propagation as described in [34] and [51]. Further details about the experimental procedure for the determination of the EWF in AHSS sheets are published in previous works [14, 34, 35, 49-51].

The thickness strain of the DENT specimens was evaluated according to Equation 7:

$$\varepsilon_{3f DENT} = \ln \left(\frac{t_0}{t_f} \right) \quad \text{Equation 7}$$

where t_0 is the initial sheet thickness and t_f is the thickness at fracture measured from the fracture surface (Figure 5b). The thickness measurements were performed at different locations and the evolution of $\varepsilon_{3f DENT}$ as a function of the distance from the crack tip was evaluated [51]. Two different terms were

identified: the thickness strain at crack initiation ($\epsilon_{3f DENT}^i$) and the thickness strain for the stable crack propagation ($\epsilon_{3f DENT}^p$).

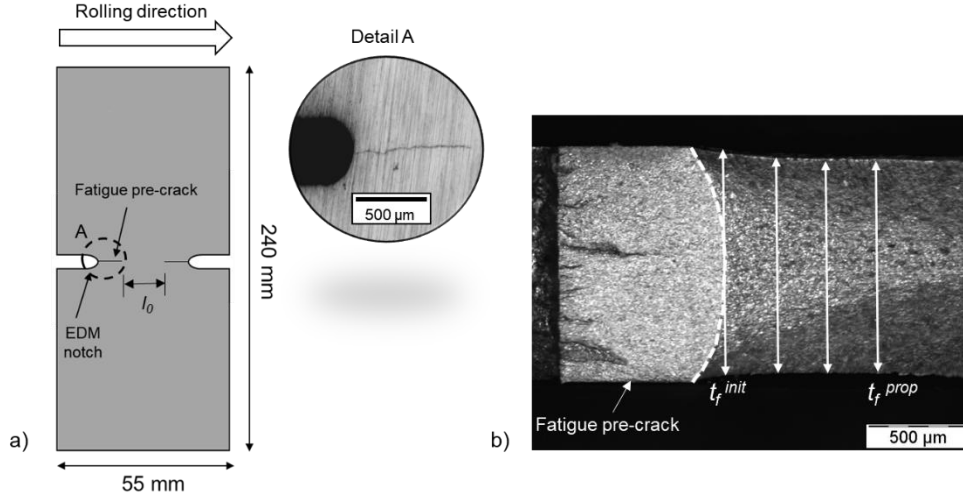

Figure 5. a) DENT specimen used for EWF tests and detail of the fatigue pre-crack at the notch. b) Fracture surface of a DENT specimen and location of the different thickness measurements. The dashed line indicates the crack tip.

2.2.3. Hole Expansion Tests

Hole expansion tests (HET) were performed according to ISO 16630 [18]. Square samples 100x100 mm with an initial punched hole 10 mm in diameter in the centre were used (Figure 6a). According to standard recommendations, the hole was punched using a punch-to-die clearance of $12 \pm 2\%$. The hole expansion was performed using a conical expansion tool with a top angle of 60° . The tests were conducted in a universal testing machine at displacement rate of 1 mm/s and were stopped after the first through-thickness crack was observed. Crack formation was detected by using a high resolution video camera (Figure 6). A minimum of 5 specimens per material were tested. The limiting hole expansion ratio (*HER*) was obtained as follows:

$$HER = \frac{D_h - D_0}{D_0} \times 100 \quad \text{Equation 8}$$

where D_h is the hole diameter after failure and D_0 is the initial hole diameter. D_h was measured from the images of the video camera by using a digital image analysis software (Figure 6d).

Furthermore, thickness measurements at the crack edge were performed by sectioning the cracks of HET specimens after the test, as suggested in [54]. Figure 6e shows a longitudinal section of a crack and the thickness measurements performed at different distances from the punched hole edge. Thickness strains were calculated in the same manner as described above for DENT specimens (Equation 7).

3. Results

3.1. Uniaxial tensile properties

Figure 7 shows the engineering and true stress-strain curves for the 6 AHSS grades investigated. True stress-strain curves are represented up to the uniform strain and linearly extrapolated to the true fracture strain. The fracture stress was calculated by dividing the load at fracture by the fracture area. The mechanical properties are summarized in Table 4.

DP780 shows comparable YS and UTS but lower elongation (both uniform and total) and $UTS \times TE$ than TRIP780. Both steels also show similar strain hardening exponent (calculated between 2 and 4% of deformation) and *TFS*. DP980 shows higher strength and lower elongation than 780MPa steel grades. However, it exhibits higher *TFS*. Despite their higher strength, 3rd Gen 1180 MPa steel grades show greater uniform and total elongation values than DP980. The 3rd Gen DP1180 presents lower YS, slightly higher UE/TE and the same UTS level than 3rd Gen TBF1180. 3rd Gen Q&P1180 has similar elongation to 3rd Gen TBF1180 but higher YS and slightly lower UTS. 3rd Gen DP1180 shows the greatest $UTS \times TE$ product of the three 1180MPa grades. On the other hand, 3rd Gen Q&P1180 shows the greatest *TFS* of the investigated steel grades.

Figure 7. Engineering (left) and true (right) stress-strain curves for the investigated AHSS grades.

Table 4. Mechanical properties for the transverse direction. YS = yield stress; UTS = ultimate tensile strength; UE = uniform elongation; TE = total elongation (initial gauge length of 80 mm); n_{2-4} = strain hardening exponent between 2 and 4% deformation; TUE = true uniform strain; TFS = true fracture strain; TTS = true thickness strain.

Steel	YS [MPa]	UTS [MPa]	YS/UTS [-]	UE [%]	TE [%]	n_{2-4} [-]	TUE [-]	TFS [-]	TTS [-]	$UTS \times TE$ [MPa*%]
DP780	513	823	0.62	14.2	19.9	0.20	0.13	0.48	0.45	16378
TRIP780	542	851	0.64	20.7	25.8	0.20	0.19	0.49	0.25	21956
DP980	816	1055	0.77	6.54	9.7	0.13	0.06	0.57	0.57	10234
3 rd Gen DP1180	895	1212	0.74	10.5	14.3	0.15	0.10	0.49	0.51	17332
3 rd Gen TBF1180	987	1216	0.81	9.2	12.6	0.11	0.09	0.55	0.57	15322
3 rd Gen Q&P1180	1034	1191	0.87	9.2	13.1	0.09	0.09	0.63	0.64	15602

3.2. Fracture toughness

3.2.1. Essential Work of Fracture

Figure 8 shows the results from EWF tests. w_e and w_e^i values are given in Table 5. TRIP780 shows one of the lowest w_e of the investigated steels, comparable to that of 3rd Gen DP1180 and 3rd Gen TBF1180. DP780 has slightly greater w_e , similar to DP980 ($w_e \approx 150$ kJ/m²). 3rd Gen Q&P1180 presents the greatest w_e . Concerning the fracture toughness at crack initiation, the trend is similar to the one observed for w_e . TRIP780, 3rd Gen DP1180 and 3rd Gen TBF1180 have slightly lower w_e^i than DP780 and DP980 while 3rd Gen Q&P1180 shows the greatest w_e^i . DP780 and DP980 present the highest contribution from crack propagation resistance after initiation ($w_e^i/w_e \approx 0.80$). In 3rd Gen DP1180 and 3rd Gen TBF1180 steels, such contribution is lower ($w_e^i/w_e \approx 0.90$). For the steels TRIP780 and 3rd Gen Q&P1180, the energy for crack initiation represents 0.98 and 0.94 of the total fracture energy, respectively.

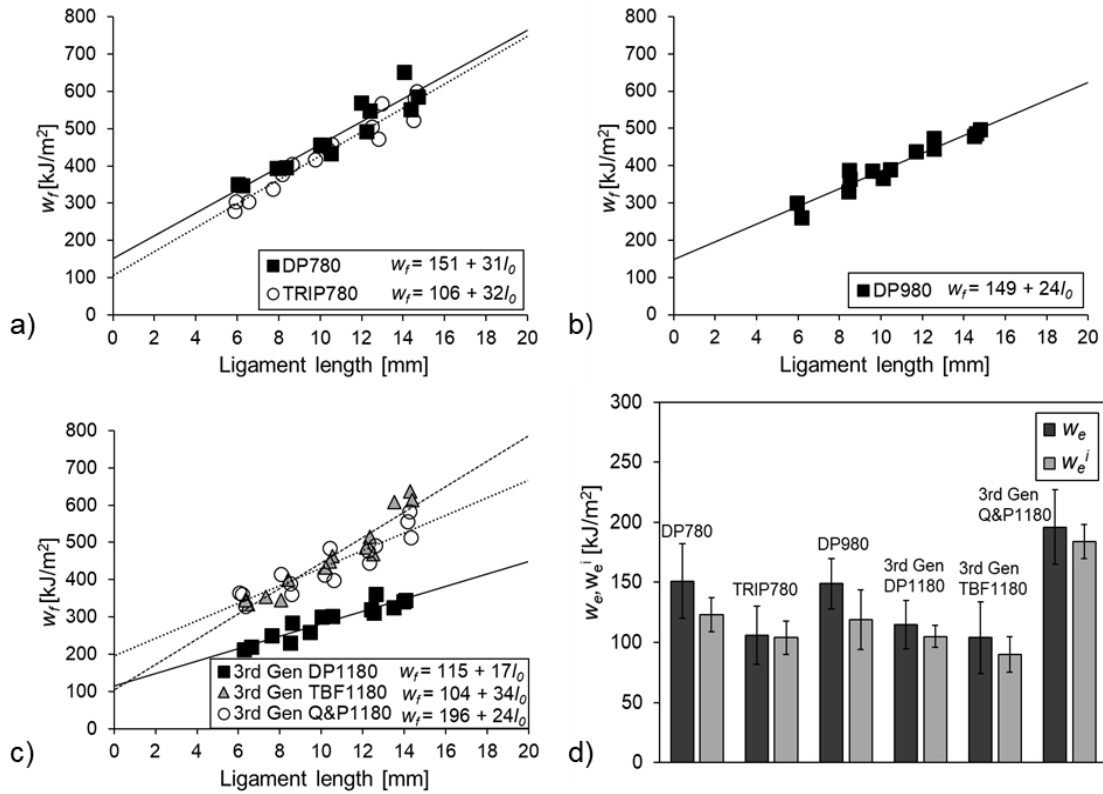

Figure 8. w_f as a function of the ligament length (l_0) for: a) 780 MPa, b) 980 MPa and c) 1180 MPa steel grades. d) w_e and w_e^i for all the investigated AHSS grades.

3.2.2. Fracture thickness strain from DENT specimens

Thickness strain of DENT specimens is plotted in Figure 9 as a function of the distance from the crack tip. ϵ_{3fDENT}^i and ϵ_{3fDENT}^p values are summarized in Figure 9d and Table 5.

ϵ_{3fDENT}^i corresponds to the value of ϵ_{3fDENT} at the crack tip (distance from crack tip = 0 mm). As observed in Figure 9a-c, ϵ_{3fDENT} reaches a constant value, corresponding to the stable crack propagation, around 0.4-0.5 mm from the crack tip. ϵ_{3fDENT}^p is an average of ϵ_{3fDENT} for a crack tip distance between 0.4 and 0.8 mm.

The steels DP780, TRIP780, DP980 and 3rd Gen Q&P1180 present similar thickness strain at crack initiation ($\epsilon_{3fDENT}^i \approx 0.08$). 3rd Gen DP1180 and 3rd Gen TBF1180 show lower ϵ_{3fDENT}^i (≈ 0.05). DP780 also exhibits the greatest thickness strain for the crack propagation, followed by 3rd Gen Q&P1180 and TRIP780. Finally, DP980, 3rd Gen DP1180 and 3rd Gen TBF1180 present the lowest ϵ_{3fDENT}^p .

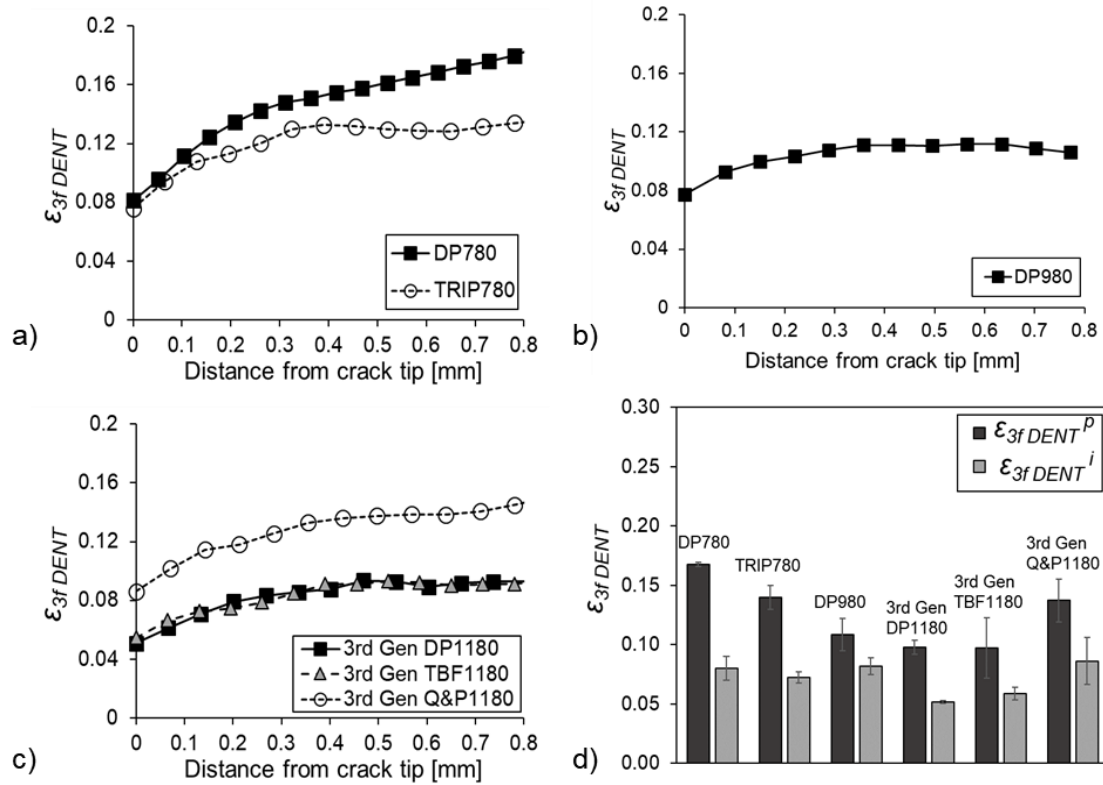

Figure 9. ϵ_{3fDENT} as a function of the distance from the crack tip for: a) 780 MPa, b) 980 MPa and c) 1180 MPa steel grades. d) ϵ_{3fDENT}^i and ϵ_{3fDENT}^P for all the investigated AHSS grades.

3.3. Hole Expansion tests

The measured HER values are shown in Figure 10a and Table 5. The results are the average of 5 specimens. The standard deviation is indicated (error bars). The Q&P steel exhibits the greatest HER , followed by DP980 and DP780. The latter shows very similar HER as 3rd Gen DP1180 and 3rd Gen TBF1180. The TRIP780 steel presents the lowest HER among the investigated steels.

In Figure 10b-d, the thickness strain measured from HET specimens is plotted as a function of the distance from the punched hole edge. Because of the lower thickness in the shear affected zone (SAZ), the values of thickness strain are higher near the hole edge. After an initial transition, the thickness strain stabilizes at a distance of approximately 0.5-0.6 mm from the edge. To avoid the influence of the SAZ in thickness measurements, thickness strain for HET specimens was determined for a distance between 0.5 and 1.5 mm. The values of true thickness strain in HET specimens (TTS_{HET}) are summarized in Table 5.

Small differences can be appreciated in TTS_{HET} for the investigated AHSS grades. Most of the steels (DP780, DP980, 3rd Gen DP1180 and 3rd Gen TBF1180) present similar thinning at fracture in HET specimens ($TTS_{HET} \approx 0.11$). 3rd Gen Q&P1180 and TRIP780 show the highest and lowest TTS_{HET} , respectively.

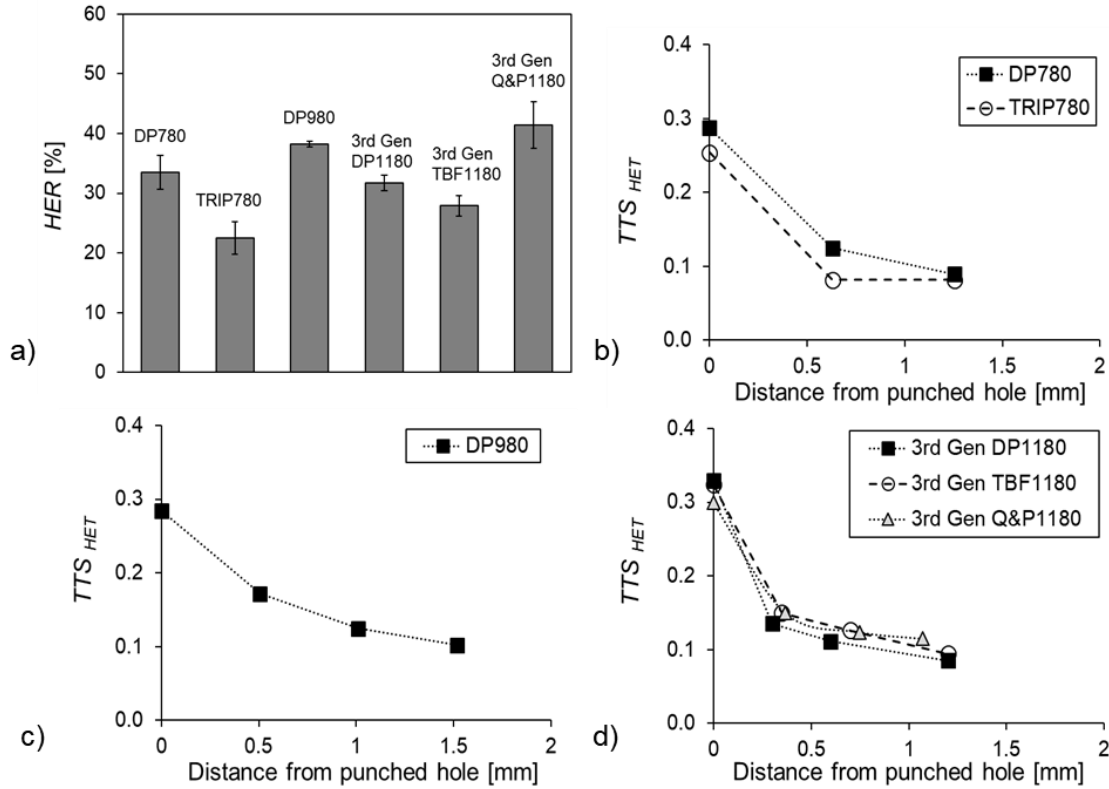

Figure 10. a) Hole expansion ratio values for the investigated AHSS grades. b, c, d) Thickness strain near the crack measured from HET specimens.

Table 5. Results from EWF tests and HET

Steel	EWF		Thickness strain DENT		HET	
	w_e^i [kJ/m ²]	w_e [kJ/m ²]	ε_{3fDENT}^i [-]	ε_{3fDENT}^p [-]	HER [%]	TTS_{HET} [-]
DP780	123 ± 14	151 ± 31	0.08 ± 0.01	0.17 ± 0.00	34 ± 3	0.11 ± 0.03
TRIP780	104 ± 14	106 ± 24	0.07 ± 0.00	0.14 ± 0.01	23 ± 3	0.08 ± 0.00

4. Discussion

4.1. Effect of the microstructure on mechanical properties and fracture resistance

The mechanical properties of AHSS are closely related to their complex multiphase microstructures. The two investigated 780 MPa steel grades, DP780 and TRIP780, have similar microstructures consisting of a ferritic-bainitic matrix with presence of martensite islands and different RA contents. The greater content of RA in TRIP780, leads to higher uniform and total elongation compared to DP780 (Figure 7), thanks to the contribution of the TRIP effect. The beneficial influence of TRIP effect on mechanical properties is associated to the formation of additional geometrically necessary dislocations during the strain-induced martensitic transformation, which increases work hardening and delays the

onset of necking [55,56]. The amount of dislocations generated depends on the amount of the RA transformed. Therefore, a higher RA volume fraction implies a higher contribution of the TRIP effect to the mechanical performance. The relation between the RA content and uniaxial tensile strength and ductility is illustrated in Figure 11; the higher the RA content, the higher the $UTS \times TE$ product.

In DP980, part of the ferrite is replaced by tempered martensite and the amount of martensite is increased respect to DP780 and TRIP780, resulting in higher strength and lower elongation. DP980 has the lowest amount of RA. Therefore, the contribution of the TRIP effect to the uniform and total elongation is limited compared to the other steel grades. The substitution of the soft ferrite by bainite or tempered martensite in 3rd Gen 1180 MPa steels allows attainment of higher strength levels, while the strain-induced transformation of RA to martensite, significantly improve the ductility compared to DP980.

The advantageous effect of RA and the strain-induced transformation to martensite on strength and ductility has been reported in several works [55, 57-60]. Nevertheless, the contribution of TRIP effect to fracture resistance is not so evident as shown in Figure 11. The figure shows no direct correlation of RA volume fraction with the TFS or the fracture toughness (w_e). For instance, looking at 1180 MPa steel grades, it can be seen that the 3rd Gen Q&P1180 shows the highest TFS and w_e , whereas it has the lowest amount of RA. The same applies for 780 MPa steel grades. Despite the larger RA content of TRIP780 it shows similar TFS and lower w_e than DP780. This finding points out the limited, or even negative, impact of RA on edge formability and crash performance.

Xiong et al. [60] also observed that, for a Q&P steel quenched at different temperatures, the $UTS \times TE$ product increased with increasing the RA content, while fracture toughness decreased. This detrimental effect of RA on cracking resistance is attributed to the higher stress triaxility present in the crack tip which significantly increases the RA to martensite transformation rate. Consequently, the brittle network of fresh martensite created in the fracture process zone favors damage and rapid crack propagation [59,60]. Different studies revealed that other factors, such as the RA morphology, size or stability also have influence on fracture resistance of TRIP-assisted steels [48,59-61].

However, fracture resistance is not only controlled by RA content and stability but also by matrix characteristics and secondary phases distribution. The work of de Diego-Calderon et al. [61] showed that crack initiation in Q&P steels is mainly controlled by the tempered martensite grain size and volume fraction, which increases the plastic strain energy to form micro-ductile structures and by the untempered martensite island formed during Q&P cycle, which act as cleavage initiation sites. According to this, the larger amount of fresh martensite present in the 3rd Gen DP1180 probably has a negative effect on TFS and w_e . On the other hand, the more homogeneous carbon-depleted martensite matrix of 3rd Gen Q&P1180 contributes to increase the fracture resistance. Therefore, to obtain an optimum balance between fracture resistance and global formability, the RA volume fraction and stability as well as the matrix characteristics, should be carefully controlled.

Figure 11. Relation of RA content with strength/ductility and fracture resistance parameters.

4.2. Correlation between stretch flangeability and fracture resistance parameters

The identification of the material properties governing the stretch flangeability of AHSS has been the focus of extensive research [14,17, 28-33,51]. As mentioned before, the *HER* has become the most widespread parameter for stretch flangeability and edge cracking resistance assessment of AHSS. However, while it is a very useful parameter for material ranking, it is not an intrinsic material property and depends on many variables. For this reason, constant efforts are devoted to correlate the *HER* with mechanical properties. Contrary to the observations for low strength steels [62], conventional uniaxial tensile properties such as tensile strength or elongation are not good indicators of *HER*. This is also shown in Figure 12, where the *HER* values measured in this work are plotted against different tensile properties (*UE*, *TE*, *UTSxTE*) and fracture resistance parameters (*TFS*, *TTS*, w_e). The figure shows that the *HER* decreases with increasing *UE*, *TE* and *UTSxTE* product, which is opposite to the initial expectations. On the other hand, fracture resistance parameters such as the *TFS*, the *TTS* or the w_e are more suitable to rationalize stretch flangeability of AHSS, i.e. the higher the fracture resistance the higher the stretch flangeability. An especially good linear correlation is observed between *HER* and w_e ($R^2=0.79$), which is in good agreement with the results of Casellas et al. [14] and Frómeta et al. [15]. For the sake of comparison, the w_e and *HER* values obtained in this work are plotted, together with the results of [14] and [15], in Figure 13. Unpublished results for different HSLA steels are also included. The very good linear fitting for different AHSS families ($R^2=0.91$) strengthen the hypothesis that stretch flangeability of AHSS is mainly dictated by fracture toughness, measured here in terms of w_e , which controls the propagation of the microcracks generated during hole punching (or edge cutting). It is important to remark that *HER* values do not only depend on material properties but also on hole preparation method, edge quality, etc. Consequently, deriving definitive conclusions only from HETs may sometimes lead to misleading material ranking and non-optimum material selection. In turn, fracture toughness is the material property that controls cracking resistance and represents a more objective design parameter for microstructural optimization in terms of fracture resistance.

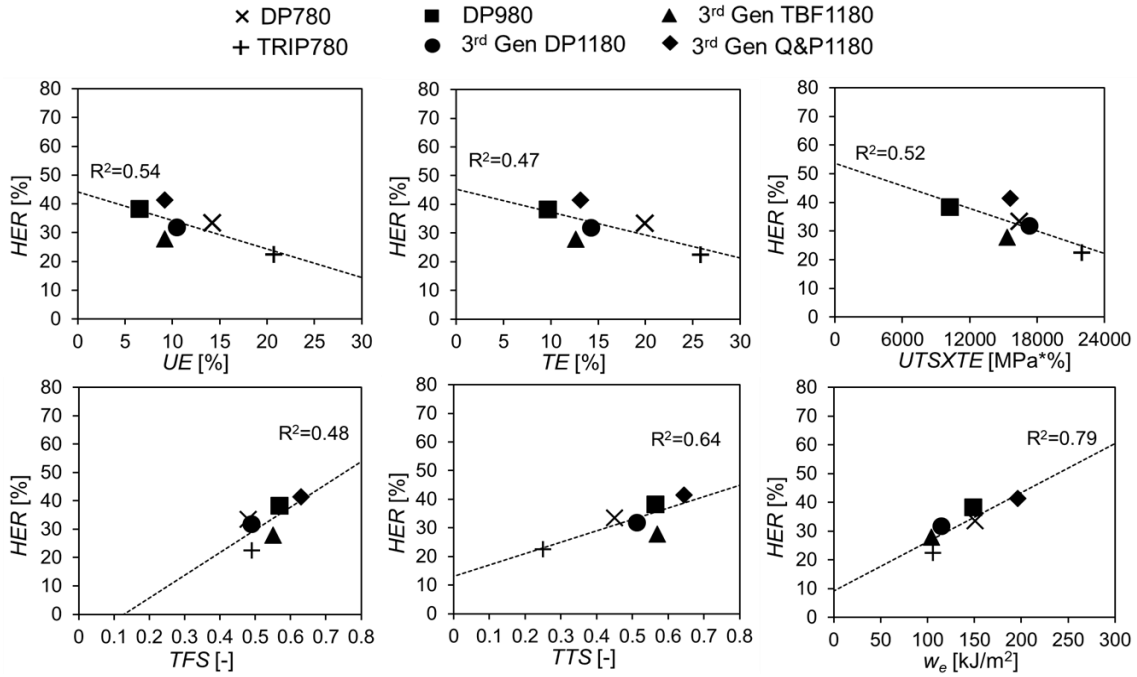

Figure 12. HER values as a function of different uniaxial strength/ductility and fracture resistance parameters

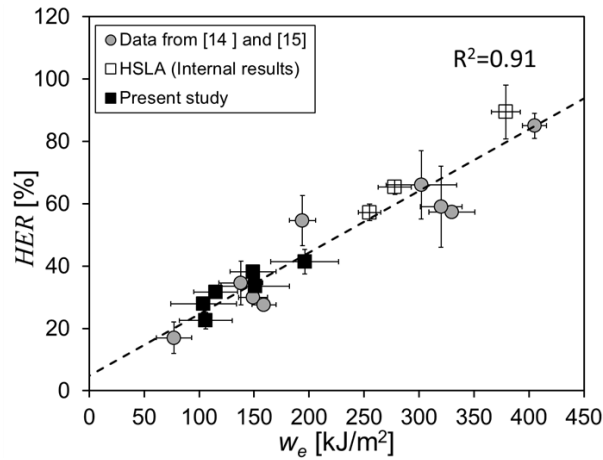

Figure 13. Correlation between HER and w_e for the AHSS grades investigated in this work together with previously published results by the authors [14, 15]. Internal unpublished results for HSLA are also plotted. All the HER values shown are from HETs according to ISO16630.

4.3. Thickness strain measurements

Figure 14 compares the thickness strains measured in HET, DENT and uniaxial tensile specimens. For all the investigated AHSS grades, the values of thinning measured in HET specimens (TTS_{HET}) are within the range of thickness strain measurements from DENT specimens ($\epsilon_{3f,DENT}^i$ and $\epsilon_{3f,DENT}^p$). It suggests that fracture mechanisms involved in HET and DENT tests are phenomenologically similar; i.e. in both tests, fracture is triggered by the propagation of pre-existing cracks (microcracks around the punched hole in HET [14, 33], and fatigue pre-cracks in DENT specimens). Accordingly, the critical thinning for edge crack propagation can be directly related to the thickness strains measured in pre-cracked DENT specimens, as shown in Figure 14.

This approach can be seen as an alternative to the edge thinning limit (*ETL*) criterion proposed by Hance [54]. The *ETL* is defined as the critical thinning for edge crack propagation and is calculated according to Equation 9:

$$ETL = 1 - \exp \left[\frac{-\ln \left(1 + \left(\frac{HER_{LB}}{100} \right) \right)}{R_m + 1} \right] \quad \text{Equation 9}$$

where HER_{LB} is the lower-bound *HER* [54] and R_m is the normal anisotropy.

If the *ETL* is exceeded anywhere along the edge of a deformed blank, or a punched hole in this case, then there is high risk of edge cracking. Figure 14 plots the calculated *ETL* values for the steels investigated in the present work. As observed, *ETL* values are in good agreement with TTS_{HET} and ϵ_{3fDENT} . Therefore, thickness strain measurements in pre-cracked DENT specimens can be used to establish a limit edge-crack thickness strain which, like the *ETL* criterion, can be implemented in FEM software as an objective and physically motivated criterion for edge-cracking prediction. Establishing a comparison between this criterion and the edge thinning diagram proposed by Hance [54], the lower safe limit for edge crack prediction would be dictated by the ϵ_{3fDENT}^i . Below this thickness strain the component would be safe from edge cracking. The upper limit for failure would be given by DENT ϵ_{3fDENT}^p . The range between ϵ_{3fDENT}^i and ϵ_{3fDENT}^p , would indicate risk of cracking.

As shown in Figure 14, the values of *TTS* from uniaxial tensile specimen completely overestimate the thickness strains from DENT and HET specimens ($TTS=0.25-0.64$). However, looking at the relative differences between the different steel grades, it can be observed that the thickness strain values for the three different test configurations follow a similar trend. This evidences that, whereas the *TTS* cannot be directly used to estimate the thickness reduction in DENT and HET specimens, it can provide a qualitative ranking in terms of fracture toughness and edge fracture resistance.

These observations may help to better understand the relationship between edge fracture and crack propagation resistance in AHSS. However, other factors such as the influence of cutting or punching conditions on limit edge thinning values should be investigated in further detail to define a reliable fracture criterion for edge crack prediction, considering initial edge damage and crack propagation resistance.

Figure 14. Thickness strain measurements performed in DENT, HET and uniaxial tensile specimens. Edge thinning limit (*ETL*) values are also plotted.

4.4. Relation between tensile properties and fracture toughness

As discussed above, fracture toughness is a relevant property to assess the fracture resistance of AHSS. Unfortunately, as shown in Figure 15, there is no a direct relationship between fracture toughness and conventional uniaxial tensile properties [48,51,60]. It is clearly shown that elongation values (uniform and total) or the $UTS \times TE$ product, which is usually used as a toughness indicator, are not suitable parameters to estimate the cracking resistance of AHSS. On the other hand, as previously observed for edge fracture resistance (Figure 12), local strain measurements from uniaxial tensile tests (TFS , TTS) give a better estimation of fracture toughness. Nevertheless, previous works showed that these fracture related parameters often cannot accurately describe the fracture behavior of the material when it is related to the presence of existing cracks or defects [51,60]. Therefore, to better understand the fracture performance of AHSS sheets, including crack initiation and propagation resistance, fracture toughness should be properly measured in the frame of fracture mechanics.

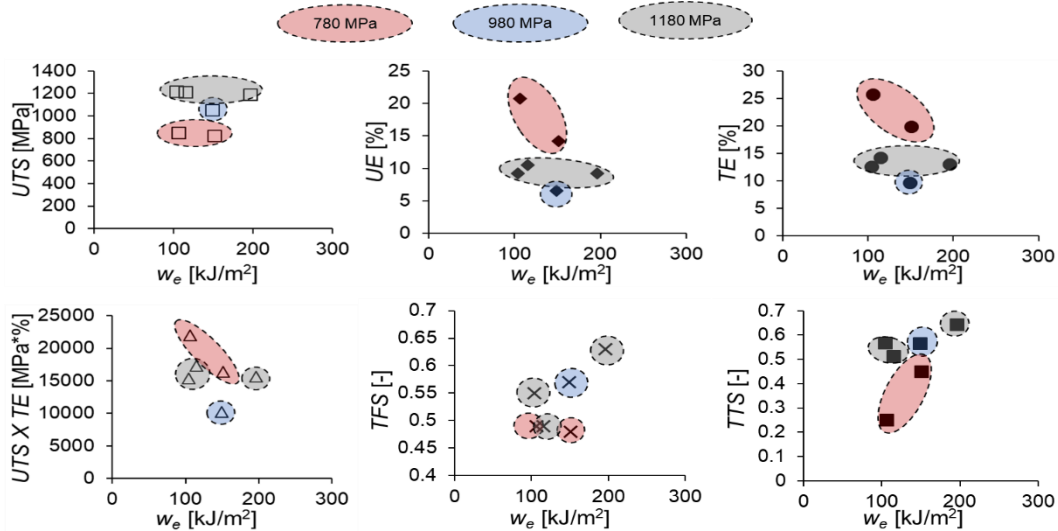

Figure 15. Correlation between fracture toughness and uniaxial tensile properties.

4.5. AHSS classification according to their crack propagation resistance

The need for new classification mappings based on formability and fracture performance of AHSS has become more and more evident in the last years [16,17, 30,31]. The concept of a global/local formability map for AHSS was introduced by Hance [16], who proposed a novel diagram for AHSS performance classification. The global formability was represented in terms of uniform elongation, which is a suitable measure of the material resistance against strain localization or necking, and local formability was indexed on the basis of the TFS . The ratio between uniform strain and TFS provides a general idea about the overall formability of the material. Alternatively, Larour et al. [30] and Heibel et al. [31], suggested the use of the true thickness strain (TTS), for local formability prediction, based on the good correlation between TTS and HER . Heibel et al. [31] stated that thickness strain measurements are more accurate than fracture strains based on the reduction of area (TFS or Z -value), since they do not take into account the fracture width, which is only influenced by global formability. They developed a formability mapping using the TTS and the true uniform strain (ϵ_u) as a measure of local and global formability, respectively.

However, none of these classification approaches consider the material's crack propagation resistance which, as shown in the present work and in previous publications [14,15, 34, 35, 51], provides useful information about the overall fracture behavior of AHSS sheets. According to this, an alternative performance mapping approach accounting for the crack propagation resistance is proposed in Figure 16. The figure plots the uniform elongation (UE) in the x-axis and the specific essential work of fracture (w_e) in the y-axis. The specific essential work of fracture is raised as an index of local formability or cracking resistance. i.e. the higher the w_e the higher the cracking resistance. The diagram is divided in different quadrants according to global and local formability levels. The more to the right in the plot the greater the global formability, whereas upper quadrants indicate superior fracture resistance and damage tolerance. Compared to traditional classification diagrams based only on tensile strength and elongation values, such as the so-called "banana" plot (Figure 17a), this classification system allows a more complete description of the formability and fracture performance of AHSS (Figure 17b). Moreover, it can serve as a guide for future steel development and optimum material selection for automotive structural parts.

Figure 16. AHSS classification based on global formability (UE) and fracture resistance (w_e). LGF: low global formability, LCR: low cracking resistance, HGF: high global formability, HCR: high cracking resistance.

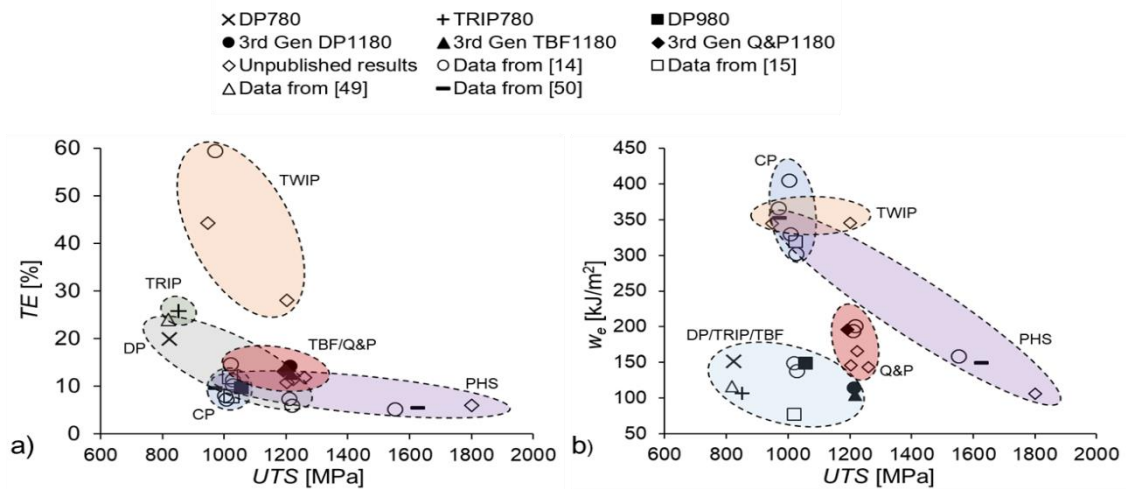

Figure 17. a) Conventional classification diagram of AHSS steels ("banana plot") in terms of UTS and TE . b) Proposed diagram for classification of AHSS according to their strength level (UTS) and fracture resistance (w_e).

5. Conclusions

The mechanical properties and the fracture resistance of different 1st and 3rd generation AHSS grades have been investigated. From the analysis of the obtained results the following conclusions can be drawn:

- Conventional uniaxial tensile properties are not sufficient to describe the local formability and fracture behavior of AHSS. On the other hand, other fracture-related parameters such as the true fracture strain (TFS), the true thickness strain (TTS) or the specific essential work of fracture (w_e) provide a better prediction of fracture performance. The very good correlation between w_e and HER values for several AHSS and HSLA steels, consolidates the observations made in previous work and confirms the close relationship between fracture toughness and stretch-flangeability in AHSS.
- A new classification mapping considering global ductility (UE) and fracture resistance (w_e) is proposed for a more exhaustive description of the overall formability and fracture behavior of AHSS. The proposed diagram can be useful for improved AHSS performance ranking and optimum material selection depending on the requirements of the intended application.
- The true thickness strain (TTS) from uniaxial tensile tests significantly overestimates the thickness reduction in punched hole edge and fatigue pre-cracked DENT specimens. However, the relative differences in TTS are well reflected in toughness and edge cracking resistance parameters. Therefore, it might be used as a qualitative indicator of fracture toughness and edge fracture resistance.
- The values of thickness strain measured in fatigue pre-cracked DENT specimens (ϵ_{3fDENT}) are similar to edge thinning values measured in HET specimens (TTS_{HET}). This evidences the similarity between edge fracture and crack propagation mechanisms and allows establishing an objective fracture criterion for edge-cracking prediction. These results highlight the importance of addressing edge cracking phenomena considering the underlying fracture mechanisms, since fracture is governed by crack propagation resistance.
- The essential work of fracture is proposed here as a relevant parameter to assess the fracture resistance of AHSS and to understand the role of microstructural constituents on fracture behavior. The investigation on the correlation between fracture toughness and uniaxial tensile properties has shown that fracture toughness cannot be estimated from traditional ductility or toughness indicators (UE , TE , $UTS \times TE$, etc.). Local strain measurements from tensile tests (TFS , TTS) offer a better estimation of fracture toughness. However, none of these parameters can accurately describe the fracture behavior in the presence of cracks. Therefore, fracture toughness, understood as the material's crack initiation and propagation resistance, must be measured following a fracture mechanics approach to properly evaluate the microstructural effects on fracture behavior.
- The results obtained from fracture toughness tests revealed that microstructural features that improve global ductility, such as for example the TRIP effect, can have a detrimental effect on fracture toughness. Hence, microstructural design must take into account not only tensile properties but also crack initiation and propagation resistance parameters.
