Abstract:

Extreme heavy precipitation events (HPEs) pose a threat to human life but remain difficult to predict. Considerable efforts to improve the forecast skills for such severe events have been made in recent years and significant progress has been realized through the development of convection-permitting numerical weather prediction (NWP) systems. However, our ability to predict such high-impact events remains limited because of the lack of adequate high frequency, high resolution water vapor (WV) observations in the low troposphere (below 3 km). Having such information will significantly improve weather forecasting and thus anticipate the floods associated with the HPEs. Indeed, HPEs occurring in small and steep watersheds are responsible for the triggering of flash floods with a sudden and often violent onset and rapid rising time, typically from 1 to 6 h following the causative rainfall.

We aim to implement an integrated prediction tool, coupling network measurements of WV profiles and a numerical weather prediction model to precisely estimate the amount, timing and location of rainfall associated with HPEs in southern France (struck by ~7 HPEs per year on average during the fall).

The proposed Water vapour Lidar Network Assimilation (WaLiNeAs) project is a unique, innovative initiative that will allow for assimilating high-vertical-resolution lidar-derived WV profiles in the first 3 km of the troposphere in a quasi-operational setting. The benefit of WaLiNeAs to the academic and operational communities is dual: advance knowledge of the complex thermodynamical and dynamical processes controlling the life cycle of HPEs and enhance the predictability of HPEs in southern France at scales relevant for meteorological studies. Increasing the accuracy of forecasts of quantitative precipitation will also help addressing a pressing societal demand.

A network of 6 autonomous Raman WV lidars will be deployed around the Western Mediterranean to provide measurements with high vertical resolution and accuracy, closing critical gaps in lower troposphere WV observations by current operational networks and satellites. Near real-time processing and ensemble assimilation of the WV data in the French Application of Research to Operations at Mesoscale (AROME-France) model, using a four-dimensional Ensemble Variational approach with 15 min updates, is expected to enhance the model capability for kilometer-scale prediction of HPEs over southern France up to 48 hours in advance.

The field campaign is scheduled to start early September 2022, to cover the period most propitious to heavy precipitation events in southern France. The Raman WV lidar

	network will be operated by a consortium of French, German, Italian and Spanish research groups. Lidar vertical profiles will be made available to Météo-France shortly after being acquired up to 96 times per day. Besides demonstrating the potential of WV lidar data assimilation in a near real-time quasi-operational context, an ancillary objective of the project is also to show that Raman lidars can be left to operate continuously almost unattended for a period of at least 3 months. It is a prerequisite in the perspective of future deployment of operational Raman lidar systems meant to fulfil the observational gaps in WV in the lower troposphere of the current operational observation networks and satellites. This project will lead to recommendations on the lidar data processing for future operational exploitation in NWP systems.

Abstract

Extreme heavy precipitation events (HPEs) pose a threat to human life but remain difficult to predict. Considerable efforts to improve the forecast skills for such severe events have been made in recent years and significant progress has been realized through the development of convection-permitting numerical weather prediction (NWP) systems. However, our ability to predict such high-impact events remains limited because of the lack of adequate high frequency, high resolution water vapor (WV) observations in the low troposphere (below 3 km). Having such information will significantly improve weather forecasting and thus anticipate the floods associated with the HPEs. Indeed, HPEs occurring in small and steep watersheds are responsible for the triggering of flash floods with a sudden and often violent onset and rapid rising time, typically from 1 to 6 h following the causative rainfall.

We aim to implement an integrated prediction tool, coupling network measurements of WV profiles and a numerical weather prediction model to precisely estimate the amount, timing and location of rainfall associated with HPEs in southern France (struck by ~7 HPEs per year on average during the fall).

The proposed Water vapour Lidar Network Assimilation (WaLiNeAs) project is a unique, innovative initiative that will allow for assimilating high-vertical-resolution lidar-derived WV profiles in the first 3 km of the troposphere in a quasi-operational setting. The benefit of WaLiNeAs to the academic and operational communities is dual: advance knowledge of the complex thermodynamical and dynamical

processes controlling the life cycle of HPEs and enhance the predictability of HPEs in southern France at scales relevant for meteorological studies. Increasing the accuracy of forecasts of quantitative precipitation will also help addressing a pressing societal demand.

A network of 6 autonomous Raman WV lidars will be deployed around the Western Mediterranean to provide measurements with high vertical resolution and accuracy, closing critical gaps in lower troposphere WV observations by current operational networks and satellites. Near real-time processing and ensemble assimilation of the WV data in the French Application of Research to Operations at Mesoscale (AROME-France) model, using a four-dimensional Ensemble Variational approach with 15 min updates, is expected to enhance the model capability for kilometer-scale prediction of HPEs over southern France up to 48 hours in advance.

The field campaign is scheduled to start early September 2022, to cover the period most propitious to heavy precipitation events in southern France. The Raman WV lidar network will be operated by a consortium of French, German, Italian and Spanish research groups. Lidar vertical profiles will be made available to Météo-France shortly after being acquired up to 96 times per day.

Besides demonstrating the potential of WV lidar data assimilation in a near real-time quasi-operational context, an ancillary objective of the project is also to show that Raman lidars can be left to operate continuously almost unattended for a period of at least 3 months. It is a prerequisite in the perspective of future deployment of operational Raman lidar systems meant to fulfil the observational gaps in WV in the lower troposphere of the current operational observation networks and satellites. This project will lead to recommendations on the lidar data processing for future operational exploitation in NWP systems.

Introduction

Heavy precipitation events (HPEs) pose a threat to human lives (e.g., Llasat et al. 2013) as well as the economy and the environment of impacted regions. HPEs occurring in small and steep watersheds are responsible for the triggering of flash floods with a sudden and often violent onset and rapid rise of rivers, typically from 1 to 6 h following the causative rainfall (Gaume et al., 2009). Flash floods and landslides lead to fatalities, loss of crops and livestocks, damage to infrastructures, as well as disruption of transport and communication. HPEs remain difficult to predict. Considerable efforts to improve the forecast skill for such severe events have been made in recent years and significant progress has been realized through the development of kilometer-scale numerical weather NWP systems (Ducrocq et al., 2014) and data assimilation techniques (e.g. Kwon et al., 2018, Gustafsson et al., 2018). However, our ability to predict such high-impact events remains limited because of the lack of adequate high

frequency, high resolution vertically resolved water vapor (WV) observations in the low troposphere to be assimilated in NWP systems, and especially in the boundary layer (Weckwerth et al., 2004; Wulfmeyer et al., 2015; Leuenberger et al., 2020).

The implementation of an integrated prediction tool, coupling network measurements of WV profiles and a NWP model, to precisely estimate the amount, timing, and locations of rainfall associated with HPEs up to 48 hours in advance, is a strong societal demand, especially in regions of France most exposed to heavy rainfall (defined as maximum accumulation in excess of 150 mm per day, Ricard et al., 2012) as those located along the Mediterranean coast. Figure 1 shows the geographical distribution of HPEs obtained from raingauges for the period 1970-2019) in Southern France. Over this period, HPEs are most numerous in Languedoc-Roussillon, along the southern edge of the Cevennes range, between the Mediterranean coastline and the southern Alps, and along the eastern side of Corsica. The two most important HPEs seen in Figure 1 are located in the Aude department and are related to the 12–13 November 1999 event (Nuissier et al., 2008; Ducrocq et al., 2008) and the 14-15 October 2018 event (Caumont et al., 2020). Large amounts of rainfall associated with these cases were attributed to strong synoptic forcing and associated with a quasi-stationary mesoscale convective systems (MCSs) which, for instance, led to accumulated surface precipitation reaching about 620 mm for the former event Ducrocq et al. (2008). Other remarkable events in the same area (Languedoc-Roussillon and Cevennes) are seen in the Hérault and Gard departments which are also linked to catastrophic events such as the 13-14 October 1995 and 8-9 September 2002 cases, respectively (Ducrocq et al., 2008) also related to torrential rainfall cause by stationary MCSs. In the southern Alps area, remarkable HPE cases include the Vaison-La-Romaine event in the Vaucluse department (22 September 1992) and the Côte d'Azur event in the Alpes Maritimes department (3 October 2015). In addition, two other cases are included that have been identified during the hydrological Cycle in the Mediterranean Experiment First Special Observing Period (HyMeX SOP1) on 14 and 26 October and 2012 (Duffourg et al., 2016, 2018). Finally, a famous HPE in Corsica was the 31 October-1 November 1993 case which affected the eastern side of Island with up to 450 mm of rain in a day in several locations.

Southern France is a region stricken by an average of 7 HPEs per year during the fall (September to November) (Ricard et al., 2012, Ducrocq et al., 2014) as illustrated by Figure 2 for the period 1970-2019. It is worth noting that HPEs can also occur outside of the September-November period, as for instance in December when more than an event per year can be observed. All other months exhibit less that one HPE per year, with the minimum in the monthly climatology being observed in June and July, which are the months less favorable for sustainability of HPEs (lower sea surface temperatures than in the fall and less eastward moving low pressure disturbances across the Mediterranean).

Furthermore, and in close connection with climate change issues, the analysis of extreme Mediterranean rainfall events for the French regions over the last few decades shows an intensification of heavy rainfall between 1961 and 2015 (+22% on the annual maximum daily totals) and an increase in the frequency of the strongest Mediterranean episodes, particularly those exceeding the 200 mm threshold in 24 hours (Ribes et al., 2019).

Accurate characterization of WV in the lower atmosphere is essential for quantitative precipitation forecasting associated with HPEs (e.g. Behrendt et al., 2011 and references therein). However, the spatial and temporal variability of the WV field is very high, notably due to the fact that (i) the WV field (unlike the temperature field) is not subject to mass adjustment processes and (ii) water coexists in three phases in the atmosphere. Furthermore, WV is an essential atmospheric meteorological and climatological variable but one that is still difficult to measure, as WV concentrations can vary by three orders of magnitude in the troposphere (typically from 10 g kg^{-1} near the surface to 0.01 g kg^{-1} in the upper troposphere).

Despite the undeniable contribution of microwave and infrared sounders, the assimilation of atmospheric WV-related observations from space still suffers from many limitations: (i) insufficient vertical resolution and accuracy below 3 km to describe precisely the very strong gradients of the moisture profiles observed in the lower troposphere (Chazette et al., 2014; Wulfmeyer et al., 2015), i.e. in a region key to understand convective initiation and the life cycle of heavy precipitating systems, and (ii) poor temporal sampling due to the fact that infrared and microwave sounders are embarked on meteorological satellites and cannot fully grasp the strong temporal variability of the WV field. Global Navigation Satellite System radio-occultation (GNSS RO) are observations from satellite providing information on humidity at high vertical resolution (~100 m) down to 1 km above the Earth surface through the limb sounding. However, they suffer from 3 major drawbacks that currently limit their interest for data assimilation in the French limited area operational Application of Research to Operations at MEsoscale (AROME-France) model. First, the horizontal resolution of GNSS RO products is too coarse in the troposphere (a few hundred km, as they consist of path-integrated measurements) which is not appropriate for a fine scale NWP system (e.g. AROME-France has a 1.3 km grid size, and 90 vertical levels between the surface and 10 hPa, 33 of which are below 2000 m). Second, GNSS RO observations do not allow to observe the WV in the first kilometer of the atmosphere which is of great importance for monitoring moisture upstream of HPE hotspots. Third, there are very few GNSS RO observations available in each AROME-France 1-hour assimilation window. For instance, the WV products currently assimilated from the plethora of microwave and infrared sensors on polar orbiting spacecraft only represent 15% of the data ingested in the AROME-France operational model. In

conclusion, currently available GNSS RO products are not suitable for improving HPE forecast through data assimilation.

Currently, 85% of the WV products assimilated in AROME-France come from surface stations, radar reflectivity near surface, aircraft, surface-based GNSS and radiosoundings. However, only the latter can provide vertically resolved WV profiles above the surface, and this twice a day at best. Ground-based GNSS networks only provide integrated WV contents whereas radars just provide indirect information on WV in precipitating systems. Surface stations only provide information on moisture very close to the surface and aircraft are currently very poorly equipped with moisture sensors.

Much of the AROME-France domain covers the western Mediterranean which is usually upstream of convective systems (Figure 3), while observation systems used for assimilation (radar, GNSS, SYNOP stations) are primarily terrestrial. This is a major caveat because this is where the fast-evolving evaporation and air mass moistening processes take place that are crucial to understand and anticipate the development of HPEs downstream over southern France. This explains why HPEs in Southern France are quite challenging to forecast with sufficient lead-time compatible with hazard warnings. Hence, the assimilation of data in the lower layers across the Western Mediterranean and available in near real-time will benefit prediction of HPEs at the mesoscale.

The project WaLiNeAs (Water vapor Lidar Network Assimilation) aims at bringing together French, Italian, German and Spanish scientists concerned with improving HPEs forecasts around the Mediterranean. The members of the international consortium have joined forces to tackle the issues and challenges highlighted above. This paper describes the rationale of the WaLiNeAs initiative as well as the measurement and assimilation strategies central to project. It also highlights the key expectations from the programme funded by several agencies in France, Italy, Germany and Spain.

Challenges, Objectives and Strategy

In the framework of the WaLiNeAs initiative, we aim to implement such an integrated prediction tool to enhance the forecast of HPEs in southern France. A consortium of French, German, Italian and Spanish research groups will deploy a network of 6 autonomous WV lidars for providing measurements with high vertical resolution and accuracy across the Western Mediterranean in fall 2022, closing critical gaps in lower troposphere WV observations by current operational networks and satellites. The proposed WV lidar network has been designed to account for all relevant WV sources and transport patterns known to contribute to the generation of HPEs in Southern France. This network will aim at demonstrating the benefit of the assimilation of vertically resolved WV data in the forthcoming version of the operational 1.3 km grid size AROME-France NWP system (Brousseau et al., 2016; Montmerle et

al., 2018) which enables ensemble-variational data assimilation for kilometer-scale prediction of heavy precipitation over Southeastern France (Desroziers et al, 2014). The ensemble-variational data assimilation system that will be available in 2022 will produce hourly analyses and will be operated with a rapid update cycle of assimilation of new observations at least each 15 min.

The WaLiNeAs project is a unique, innovative initiative that will allow for assimilating lidar-derived WV profiles in the lower troposphere with hectometer-scale vertical resolution in near-real time conditions for a continuous period of at least 3 consecutive months. The benefit of WaLiNeAs to the academic and operational communities is dual: advance knowledge of the processes at play in the life cycle of HPEs and enhance the predictability of HPEs in Southern France at scales relevant for meteorological studies. Both aspects are dealt with in the framework of WaLiNeAs.

Finally, the breakthrough science that will be carried out in the framework of WaLiNeAs concerns:

- characterizing the predictability of HPEs and uncertainties in the prediction of the position, evolution and the rainfall amount of the precipitating systems.
- assessing the role of water vapor distribution over the western Mediterranean on the characteristics of the moist inflow (origin, evolution, pathways) feeding deep convection leading to HPEs,
- investigating the role of Mediterranean cyclone in the water cycle and HPEs in the Western Mediterranean,
- understanding the impact of elevated tropical moist plumes on the life cycle of deep convection and related HPEs,
- advancing knowledge on the role of dry intrusions on HPE in cases of frontal precipitation,

The Raman lidar-derived WV data acquired in the framework of the WaLiNeAs project will be made available to Météo-France shortly after being acquired and will be assimilated up to 96 times per day. The focus of the project will be on providing high quality lidar-derived WV data in the first 3 km of the atmosphere, where no other observational technique can provide adequate data. To that respect, the two most cutting edge aspects of the project are: (i) the near-real time processing and qualification of the lidar data (with WV profiles in the lower troposphere available every 15 min.) and (ii) the proposed system (four-dimensional Ensemble Variational – 4DEnVar (Desroziers et al., 2014)– with kilometric resolution) for the assimilation of qualified lidar data acquired in the lower troposphere, day and night.

Besides demonstrating the potential of WV lidar data assimilation in the AROME-France system, an ancillary objective of the project is also to show that Raman lidars can be left to operate continuously almost unattended for a period of at least 3 months. It is a prerequisite in the perspective of future/further deployment of operational Raman lidar systems meant to fulfil the observational gaps

in water vapor in the lower troposphere of the current operational observation networks and satellites. This project can be considered as a test bed for the concept of operational use of Raman lidars to be assimilated in a kilometer-scale NWP system.

The WaLiNeAs project builds on previous experience of the consortium partners, namely:

- Wulfmeyer et al. (2006) have assimilated airborne WV lidar observations acquired during a case study of the International H_2O project (IHOP) with the MM5 mesoscale NWP system and its four-dimensional variational (4D-Var) assimilation system,
- Grzeschik et al. (2008) extended the previous work to the assimilation of the WV observations provided by a ground-based network of Raman lidar systems,
- Bielli et al. (2012) used a pre-operational version of the Météo-France AROME-France NWP system (Seity et al., 2011) and its associated 3D-Var high-resolution assimilation system to evaluate the impact on the quantitative precipitation forecasts of the Convective and Orographically-driven Precipitation Study (COPS) airborne lidar observations collected during July 2007. A continuous assimilation cycle updated every 3 h was run over a month to provide the initial conditions of a sequence of 30 h forecasts carried out over 19 consecutive days,
- an ambitious effort has been conducted to assimilate water vapour mixing ratio observations from the airborne lidar LEANDRE 2 (Lidar Embarqué pour l'étude des Aérosols, des Nuages, de la Dynamique, du Rayonnement et des Espèces minoritaires, developed at LATMOS, Guyancourt, France) and the two ground-based Raman lidars located in Menorca (the Weather Atmospheric LIdar –WALI- developed by LSCE, Gif-sur-Yvette, France) and Candillargues (the BASILicata Lidar – BASIL- developed by the University de la Basilicata, Potenza, Italy) as part of the reanalysis project aiming at assimilating the research observations collected during the HyMeX SOP1 (Richard et al., 2014; Fourrié et al., 2015, 2019, 2021). One month of ground-based Raman lidar data and airborne lidar observations from approximately 20 flights were used in the reanalyses conducted by Fourrié et al. (2015, 2019, 2021),
- Thundathil et al. (2020) assimilated even both water vapour and temperature lidar data into the Weather and Research Forecast model on the convection-permitting scale applying a 3DVAR rapid update cycle and found that especially the assimilation of moisture results in a significant improvement of the model fields.

All these studies have shown encouraging results in terms of the impact of lidar-derived WV data assimilation on quantitative precipitation forecasts. However, they are based on a limited number of cases, date from a limited number of lidar systems (2 at most) and too short assimilation periods to allow for general conclusions to be drawn in a statistical sense regarding the impact of WV lidar observation assimilation on the quantitative precipitation forecast.

Implementation of WaLiNeAs

As part of the WaLiNeAs initiative, the WV Raman lidars will be operated continuously during 3 months starting early September 2022, to cover the period most propitious to HPEs in southern France (see Figures 1 and 2). The duration of the operation is imposed by the necessity to have a long enough record in order for the WV profiles assimilated to have a significant impact on the moisture fields in the model forecasts. This long dataset is crucial to assess statistical errors and to genuinely evaluate the benefit of Raman lidar water vapor data assimilation for operational NWPS.

This proposal accounts for the fact that Raman lidar technology has reached the level of maturity needed for unattended, continuous operation. Since more than 10 years, automated Raman lidar systems are operated in automatic mode at several observatories and research institutions (Goldsmith et al., 1998; Balin et al., 2004; Reichardt et al., 2021; Dinoev et al., 2013; Brocard et al., 2013; Leuenberger et al., 2020). Recently, also mobile systems became available which can be moved for field experiments: This is attested by the large datasets acquired by WALI and BASIL in the field during HyMeX SOP1 (Chazette et al., 2016; Di Girolamo et al., 2020), or by the automated Raman lidar ARTHUS (Atmospheric Raman Temperature and Humidity Sounder, Lange et al., 2019) of University of Hohenheim that operated from a ship for over a month during the EUREC^{4}A campaign (Stevens et al., 2021). Figure 3 shows examples of time-height cross-sections of WV mixing ratio measured with WALI from 17 September to 28 October 2012 over Menorca, Spain (Figure 3a), with BASIL over the 12-day time period from 0000 UTC on 17 October 2012 to 0000 UTC on 27 October 2012 over Candillargues, France (Figure 3b), and with ARTHUS between 11 and 19 February 2020 on-board the research vessel Maria S. Merian over the Tropical Atlantic Ocean during the EUREC^{4}A campaign (Figure 3c). During HyMeX, WALI acquired 1000 hours of WV mixing ratio profiles while being operated continuously during SOP1 and BASIL acquired over 600 hours of data during the same period, but was operated continuously for 3 days at a time, at most. During EUREC^{4}A, ARTHUS collected useful data between 24 January and 19 February 2020, for approximately 620 hours.

We aim to operate a dedicated network of 6 autonomous Raman WV lidars over the Western Mediterranean in locations shown in Figure 4 to monitor the low-level and elevated moisture towards regions most likely to be hampered by HPEs in southern France in the fall as illustrated by Figure 5, and also discussed by Ricard et al. (2012, see their Figure 1), namely: Languedoc-Roussillon (LR), Cévennes-Vivarais (CV), southern Alpes (SA) and Corsica (CO). Five of the six Raman lidar systems will be deployed specifically for WaLiNeAs. The 6th system is operating as a fixed, long-term monitoring station. The low-level moisture pathways are inspired by the composite analysis for 40 HPEs made by Ricard et al.

(2012), for each of the target areas based on 700–1000-hPa integrated moisture flux and 925-hPa wind speed (see their Figure 11). We are considering sites such as Barcelona and the islands of Menorca in Spain (to monitor the southerly flow upwind of LR, CV and SA, as well as elevated plumes from tropical Africa), Ajaccio in Corsica (to monitor the southerly flow upwind of CO and the easterly flow upwind of LR), Narbonne in the Aude Valley (to monitor the westerly flow from the Atlantic Ocean as well as event over LR), Cannes (to monitor the easterly flow upwind LR and SA) and Montpellier (to monitor the southerly flow and boundary layer upstream of CV). The main moisture patterns leading to HPE in southern France shown in Figure 5 are also based on prior knowledge (Duffourg and Ducrocq, 2013) and on the most recent work conducted on HyMeX SOP1, e.g. Chazette et al. (2016b), Di Girolamo et al. (2016), Duffourg et al. (2018), Khodayar et al., (2018), among others. In an Observing System Simulation Experiment context, Yoshida et al. (2020) have shown that assimilating Raman lidar water vapour data on the windward side of heavy precipitation was likely to improve precipitation forecasts.

The worth of installing a Raman lidar system to monitor WV upstream of HPE-prone target area further is illustrated in Figure 6. In Figure 6a, we show the density distribution of all WV vertical profiles acquired with the WALI system installed in the city of La Ciutadella, in Menorca, during the entire HyMeX SOP1 (see Figure 4 for the location of La Ciutadella). WALI was operating upstream of target areas in Southern France, namely LR, CV and SA. The distribution highlights the spread in WV mixing ratio observed upstream of the Western Mediterranean coastline (color) around the mean profiles (black solid line). Figure 6a stresses out that in the course of the HyMeX SOP1, the highest occurrence of WV was found below 2 km amsl (where WV mixing ratio in on average comprised between 5 and 15 g kg^{-1}) and above 5 km amsl (where values are very low, less than 1.5 g kg^{-1}). The spread below 2 km amsl reaches 6 g kg^{-1} for WV mixing ratio values occurring more than 30 %, and more than doubles for WV mixing ratio values occuring more than 10% of the time. Figure 6b and 6c show the density distribution of WV mixing ratio in HPE-free conditions and in HPE conditions, respectively, for two 5-day periods. The HPE-free period selected is from 2 to 6 October 2012, during which no HPEs were observed in the Western Mediterranean basin. For the HPE conditions, we selected the period from 7 to 11 October 2012, up to 4 days ahead of HPE events observed in the CV, namely IOP12a on 11-12 October (Khodayar et al., 2018) and IOP 13 on 14-16 October (Duffourg et al., 2018). Above 2 km amsl, the WV mixing ratio distribution for the no-HPE period (Figure 6b) is skewed towards small values than in the HPE period (Figure 6c) up to 8 km amsl. the average WV mixing ratio profile, computed as the barycenters of the distributions at each altitude bin (pink and red solid lines, for the HPE-free and HPE periods, respectively), overlain in Figure 6b and 6c, are also shown in Figure 6d. They highlight that, between 0.75 and 8 km amsl, the troposphere si significantly moister in HPE conditions than in HPE-free conditions. The marine boundary layer is also slighly more moist in HPE conditions below 300 m

amsl. The integrated water vapour content profile, computed at the integral of the lidar-derived specific humidity profiles from the ground upward, in HPE-free conditions (pink solid line) and in HPE conditions (red solid line) is shown in Figure 6e. Over the depth of the lower troposphere, i.e. below 8 km amsl, the difference between HPE and HPE-free conditions reaches 10 kg m^{-2}. The integrated water vapour content in HPE conditions (~33 kg m^{-2}) are comparable to those derived from global positioning system by Khodayar et al. (2018) during IOP 12, even though slightly smaller due to the fact that we are only considering partial columns. The above analysis clearly suggests that Raman lidar-derived WV mixing ratio profiles collected in Menorca in a period up to 4 days ahead of HPEs in the CV area are significantly moister than for a 4-day period when no HPE events are observed in Southern France, thereby providing data worthy of assimilation in a HPE forecasting context.

The 5 mobile Raman lidar systems that will be operating in the field are rugged and transportable systems that have operated in many locations in recent years:

- The Weather Atmospheric LIdar (WALI, Chazette et al., 2014) developed at LSCE, which was involved in the SOP1 of HyMeX (Chazette et al., 2016a,b; Di Girolamo et al., 2020) or during the Pollution in the ARCtic System (PARCS) project (Totems et al., 2019) and recently during the Lacustrine-Water vApor Isotope inVentory Experiment (L-WAIVE) project (Chazette et al., 2020),
- The Airborne Lidar for Atmospheric Studies (ALiAS, Chazette et al., 2012; Chazette et al., 2020) developed at LSCE,
- The Lidar for Automatic Atmospheric Surveys using Raman Scattering (LAASURS; Chazette et al., 2017, 2019, 2020) developed at LSCE,
- The University of BASILicata ground-based Raman Lidar system (BASIL), which was involved in HyMeX (Di Girolamo et al., 2009, 2016, 2017, 2020; Stelitano et al., 2019),
- The Atmospheric Raman Temperature and Humidity Sounder (ARTHUS, Lange et al., 2019) of the University of Hohenheim.

The fixed Raman lidar system that will operate in Barcelona is the lidar system of Universitat Politècnica de Catalunya (UPC, Muñoz-Porcar et al. 2018, 2021) which is in operation since 1993 and is part of the European Aerosol Research Lidar Network (EARLINET) since 2000 and of the European Research Infrastructure for the observation of Aerosol, Clouds, and Trace Gases (ACTRIS) since 2011.

For details on the instruments (emission unit, reception unit, spatio-temporal sampling strategy, etc.), the reader is referred to the existing body of literature listed above and are summarized in Table 1. LAASURS and ALIAS will be upgraded to WV Raman lidar prior to the start of the fall 2022 field campaign.

The lidar data will be collected, disseminated, and monitored in real time, as would be done in an operational context. Since it is unrealistic to set up a full real-time operational NWP system dedicated to a single observing system (the cost of real-time high-performance computing with human supervision far exceeds funds allotted to WaLiNeAs), the lidar data assimilation will be evaluated in a quasi-operational environment, i.e., with the same tools and data, but without the associated resources necessary for real-time operations. This framework will allow deriving results that will hold true for an operational context, at an economic cost.

Project organisation and structure

The project is organized around 4 scientific tasks aimed at developing an innovative integrated forecasting tool in order to pave the way towards an operational, breakthrough HPE-related hazard warning capability for southern France and Corsica as well as work on the cutting-edge science linked with the development of such an innovative tool.

WP1 (field campaign) will drive the necessary experimental/instrumental deployments to achieve the acquisition of WV profiles and the near-real time transmission of the data to the French Weather Service. This will include the upgrade of the Raman lidar systems to be deployed, as well as the definition of the exact location of the implementation sites and complementary instruments, the data transmission protocols and data quality assurance as well as the characterization of system calibration. WP1 is organized around 3 main activities:

- *Upgrade and preparation of lidar systems*

The WV-Raman upgrades consist in adding a H_2O-Raman channel on each lidar and the development of an acquisition chain. The lasers will be upgraded in energy to improve the signal to noise ratio. This will ensure that the output energy of the systems as well as their performances (precision, systematic error on WV profiles, etc…) will be same as the operational WALI system. Note that these two mini-lidar systems will be autonomous and connected via Internet. Prior to the field campaign, a thorough intercomparison of WV profiles between the operational WALI Raman lidar and the upgraded Raman systems (LAASURS and ALIAS) will be undertaken.

- *Real time data processing and data transmission*

For real-time purpose, the six Raman lidars will deliver 2-4 times an hour profiles which are averaged over 15 minutes with vertical resolution of 100 m and a targeted root-mean-square-error of 0.4 g kg^{-1} in the first 3 km, day and night. Performances are expected to exceed these target values during the

night for all systems (WALI, ALIAS, LAASURS, BASIL, ARTHUS and UPC/EARLINET). In addition to the water vapor mixing ratio profiles, the statistical uncertainties of these profiles as well as the atmospheric variance determined with the auto-covariance technique (Lenschow et al., 2000) will be provided. It is a significant advantage of the lidar technique that also these error profiles can be determined and consequently be used for the data assimilation.

The WV profile acquisition, processing and transmission sequence is anticipated to span over 25 minutes (Figure 7). For the analysis at XXXX UTC, the assimilation system will ingest observations made between XXXX UTC - 30 min and XXXX UTC + 30 min. Every 15 min between XXXX UTC - 30 min and XXXX UTC + 30 min, the WV lidar data (resulting from a 15 min. average) will be processed and errors calculated within a 5 min window, and then transmitted in an additional 5 min window (Figure 7). There will be some overlap in the processing of each profile: as soon as the 15 min measurement period (in green in Figure 7) is over, there is both the start of the next 15 min measurement period and the start of the processing (5 min, in yellow) + transmission (5 min, in white framed in black) of the one that has just ended. The measuring periods for an assimilation window [XXXX - 30 min; XXXX + 30 min] would be : XXXX - 37.5 min; XXXX - 22.5 min], [XXXX - 22.5 min; XXXX - 7.5 min], [XXXX - 7.5 min; XXXX + 7.5 min], [XXXX + 7.5 min; XXXX + 22.5 min], [XXXX + 22.5 min; XXXX + 37.5 min]. So, for a cut-off time greater than or equal to XXXX + 47.5 min, there are 4 profiles for the corresponding analysis. The end of the last 5 min transmission window should occur before the so-called cut-off time. The cut-off time is the time after the hour of analysis until which one waits for the observations to arrive before starting the calculations. In the current AROME-France assimilation system, this cut-off is not constant and varies according to the time of day (it varies from T+20 min. to T+3h15). Depending on the cut-off time, up to 6 WV lidar profiles will be assimilated in each hourly 4DEnVar analysis. This sequence is subject to adaptation depending on the evolution of the high computational performances at Météo-France and performances of the WV lidars in the field.

- *WV lidars intercomparison*

After the conduct of the field campaign, the consortium will also deliver a consistent, self-coherent and validated WV dataset of lidar profiles, incl. uncertainties at high spatio-temporal resolution for data assimilation experiments. This effort will include inter-comparison of WV lidar-derived profiles between the 3 operational systems WALI, BASIL and ARTHUS. Comparison between WALI, LAASURS and ALIAS will be conducted at LSCE before and after the field campaign. The long-term stability and calibration of the WV lidar systems will also be monitored throughout the field campaign using a

mobile radiosonding unit that will be operated alongside each of the 6 Raman lidar systems at the beginning, mid-way through and at the end of the campaign.

WP2 (data monitoring) aims at Raman lidar data assimilation in AROME-France. This includes evaluating and optimizing how the observations can be used in the data assimilation system. For this, the ability of the model to simulate the physical quantity that is observed must be ensured. In practice, this is done through the "monitoring" of observations, i.e., the computation of observation-minus-background statistics, where "background" refers to short-term forecasts that will be blended with observations during the data assimilation process. Such a monitoring requires some preliminary work. To compare observations and the background, a common physical space has to be chosen, which needs to be close to that of the raw measurements to avoid the introduction of retrieval errors, while lending itself to the simulation from the model prognostic variables. The choice of this physical space in terms of geometry, physical quantity, and observation processing (time-space averaging, filtering) will be carefully assessed based on the horizontal and vertical resolutions of the current AROME-France version (e.g., 1.3 km) and the 15 min period of observations use. The current version of AROME-France uses a three-dimensional variational (3D-Var) algorithm to assimilate weather data. A four-dimensional Ensemble-Variational (4DEnVar) data assimilation system will be available in 2022 to replace the current 3D-Var data assimilation system. It will be used in place of the 3D-Var data assimilation system for the WaLiNeAs project.

A near real-time monitoring will be set up during the field campaign scheduled in the fall of 2022 that will enable the evaluation of the statistical consistency between the observations and the model background. Such a real-time monitoring is usually performed at operational weather forecasting centres to detect gross errors such as hardware failure, calibration drift, or transmission losses. The monitoring performed in the framework of WaLiNeAs will ensure that the data are collected as expected and, if needed, allow for corrective action to be taken immediately so as to minimize any data loss.

After the field campaign, observation-minus-background statistics will be performed on the consistent, self-coherent and validated dataset of lidar profiles, once it is available (**WP1**). The objective is to compare to which extent the real-time and post-processed lidar data differ with respect to the model. Depending on the results, observation-minus-background biases will be removed so as to comply with the data assimilation technique assumptions. The resulting lidar data sets and observation operator will be used in **WP3** for the data assimilation experiments.

WP3 (lidar data assimilation) is focused on the post-campaign work on the assessment of the lidar data impact in the assimilation scheme. Since the objective of the project is to prove the feasibility and benefit of assimilating lidar data in an operational context, the assessment of the impact of the lidar data assimilation will be carried out by performing data assimilation experiments with the AROME-France system. The proven methodology of Observing System Experiments will be used. It consists in running two different experiments: the reference experiment, while the data assimilation experiment will additionally assimilate lidar data. So, the reference experiment will already assimilate all routinely available observations, and thus the impact of lidar observations will translate the ability of this new observing system to complement existing observing systems. With this methodology, the impact of the lidar data assimilation is simply obtained by contrasting the weather forecasts obtained by each of the two experiments with respect to an independent observational data set (e.g., precipitation amounts measured by rain gauges).

Data assimilation experiments will be performed for the two data sets prepared in WP1 and WP2: a set of lidar data collected in real-time, and a set of consistent, self-coherent and validated lidar data. The real-time data set will provide baseline results that will show which benefit can readily be obtained with the current real-time data processing. The post-processed data set will show to which extent additional processing may improve the quality of the weather forecasts. This will likely lead to recommendations on the lidar data processing for future operational exploitation in NWP systems.

WP4 (HPE related science) is expected to provide an improved representation of the highly variable spatial-temporal distribution of WV in the AROME-France analyses from the advanced data assimilation implemented in this project, that will in turn lead to an overall improvement of the complex thermodynamical and dynamical processes controlling the life cycle of HPEs. We will investigate the impact of the WV profiles processing (real-time Vs validated lidar data) on (i) the WV distribution over the western Mediterranean in the AROME-France model, and (ii) the prediction of the position, evolution and the rainfall amount of the precipitating systems and HPEs encountered during the 3-month field campaign. The results will also be compared to AROME-France reference simulations in which lidar-derived WV profiles are not assimilated to further emphasize the worth (or lack thereof) of assimilating such data in the French NWP system. In addition, with a similar approach, we will examine what is gained in terms of advancing our knowledge of complex processes pertaining to the characteristics of the moist inflow (origin, evolution, pathways) feeding deep convection leading to HPEs. We will also study the impact of dry intrusions from the upper troposphere and moist tropical plumes on HPEs encountered during the campaign.

Outlook

This project aims at the development of all-weather, unattended, rugged and operational Raman lidar systems for smart monitoring of the environment, and WV in particular. The WaLiNeAs project aims at developing the test bed of an integrated prediction tool, coupling network measurements of WV profiles and a weather forecast model to precisely estimate precipitable water upstream of an event up to 48 hours in advance in Southern France. This project is highly innovative and will lay the foundation for a future integrated warning tool aiming to prevent natural hazards associated with HPEs as often experienced along the Mediterranean coastline. Once the proof of concept is validated in the framework of the WaLiNeAs project, similar integrated tools may be applied in other parts of the World to avoid similar natural hazards.

The highest risk for the project lies with the meteorology and the possible lack of heavy precipitation events during the fall of 2022. However, the length of the field campaign (3 months) is the best insurance that extreme events will happen somewhere in northwestern Mediterranean. Nevertheless, on average, ~ 7 HPEs (daily rainfall > 150 mm) occur every year between September and November (Ricard et al. 2012, Figure 2). Furthermore, even in the case of lower than average HPE activity in southern France, the network data will be beneficial to the AROME-France forecasts, and a positive impact is expected on average skill scores and in the case of southern maritime inflow situation. Furthermore, experience learned from the lidar data processing in near-real time and assimilation in NWP systems will still be extremely valuable to make recommendation on the use of WV lidars for future operational NWP systems. In all cases, the uttermost important objective of the project is to contribute to increase the accuracy of forecasts of quantitative precipitation in order to satisfy the societal demands in terms of amount, timing, and basin-specific locations of rainfall and flash flooding.

Acknowledgements

The authors would like to thank Evelyne Richard and Mathieu Nuret, now retired, who have contributed to the original version of the WaLiNeAs proposals submitted to ANR in 2018 and 2019.

Funding

This work is a follow-on initiative to the HyMeX programme supported by MISTRALS and the Agence Nationale de la Recherche WaLiNeAs Grant ANR-20-CE04-0001. Additional funding was also obtained from the H2020 program of the European Union (grant agreement no. 654109, 778349, 871115), the Spanish Ministry of Science and Innovation (ref. PID2019-103886RB-I00), the Spanish Ministry of

Economy, Industry and Competitiveness (ref. CGL2017-90884-REDT), and the Unit of Excellence Maria de Maeztu (ref. MDM-2016-0600) financed by the Spanish Agencia Estatal de Investigación.

Conflict of interest

On behalf of all authors, the corresponding author states that there is no conflict of interest.

Table 1: Main technical characteristics of the lidar instruments

Figures

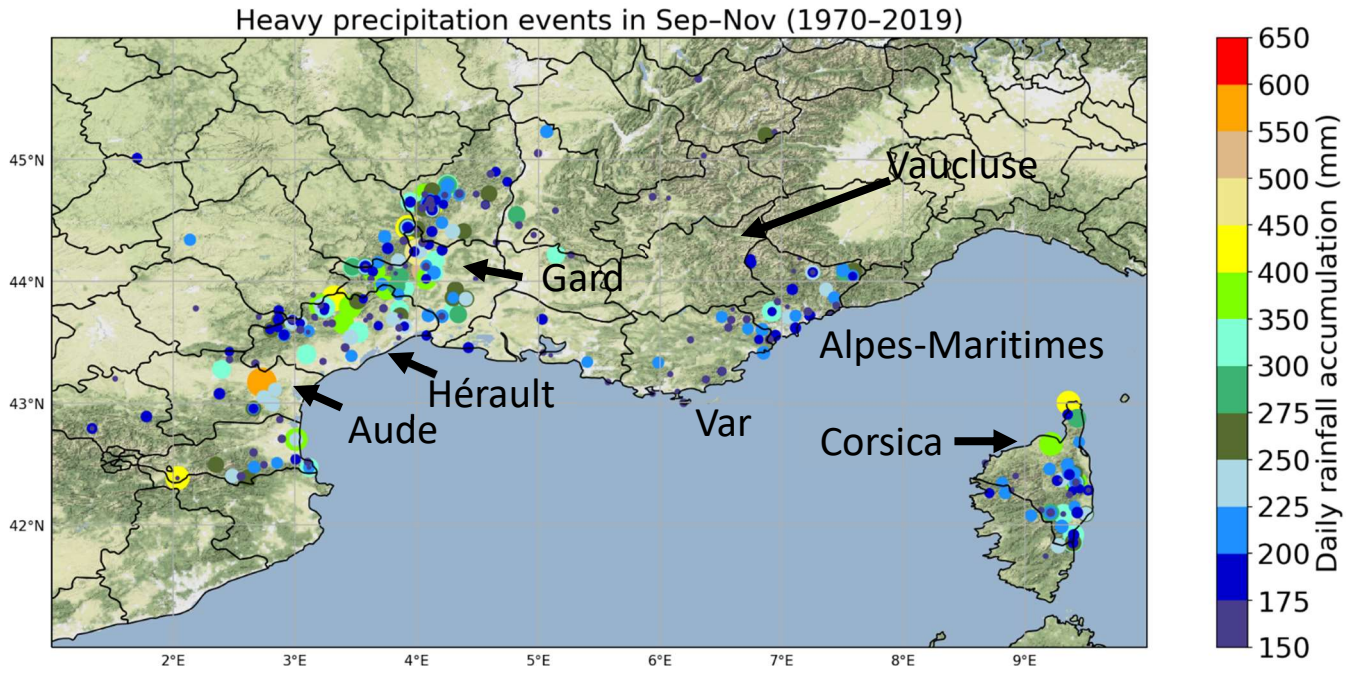

Figure 1: Geographical distribution of heavy precipitation events defined as maximum accumulation > 150 mm/day and separated from other events by a distance of more 100 km.

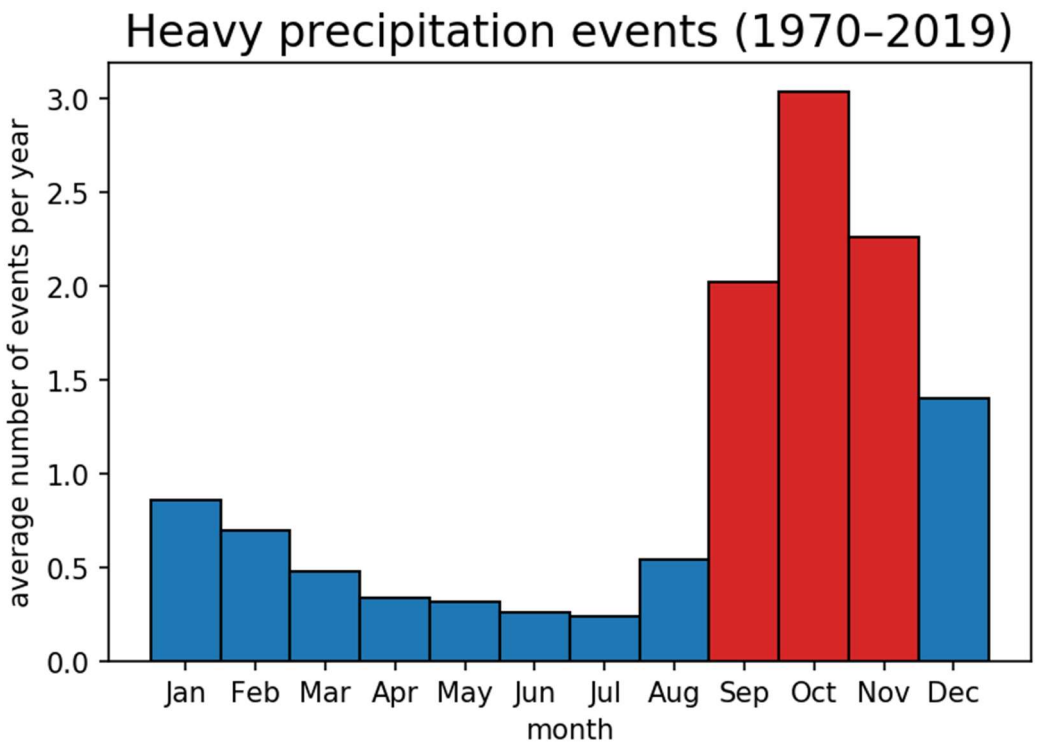

Figure 2: Frequency of monthly heavy precipitation events per year averaged over the period 1970-2019, highlighting in red the three most likely months (September-October-November).

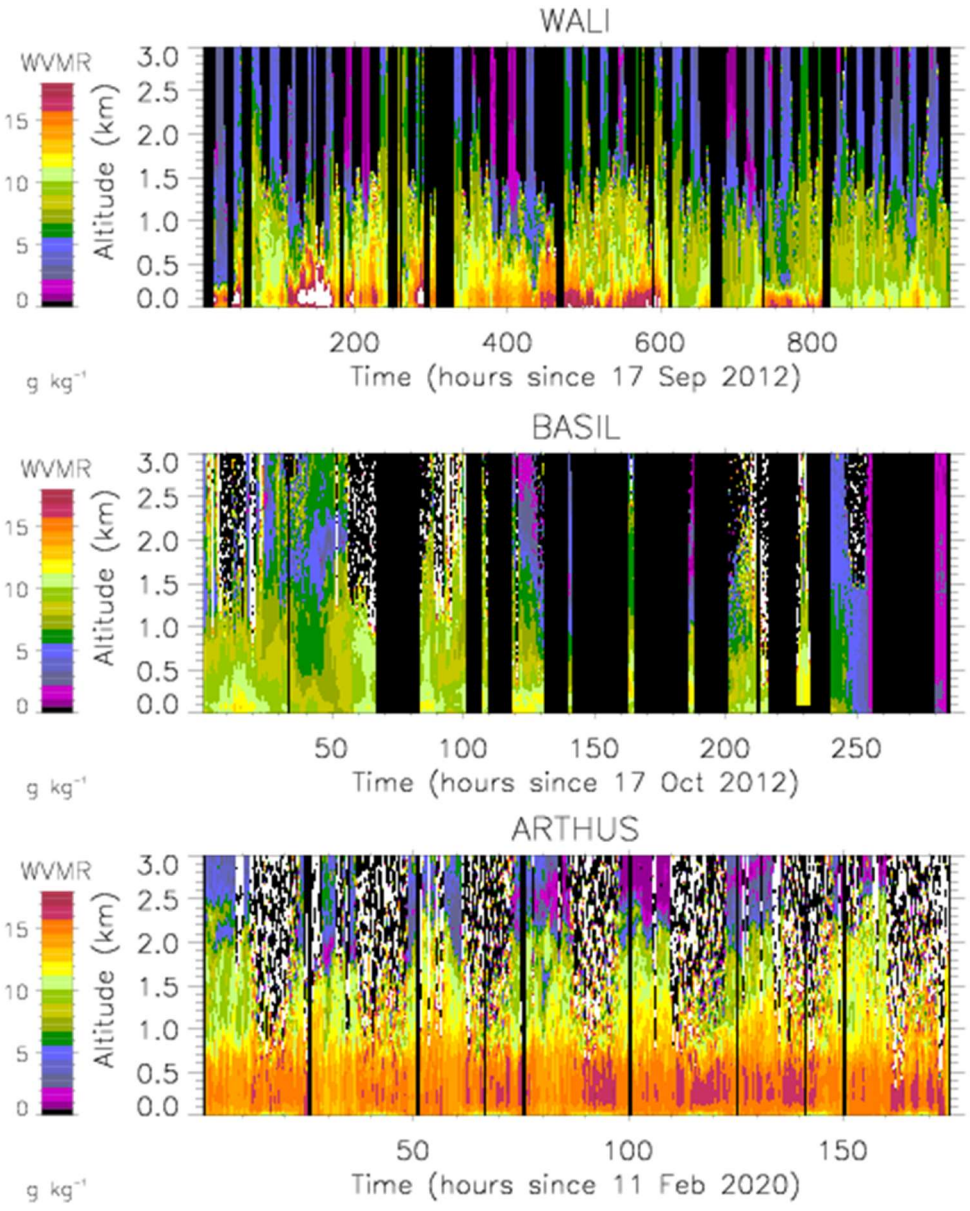

Figure 3: (a) Time-height cross-section of water vapor mixing ratio acquired during the HyMeX SOP1 with the WALI system of LSCE (~1000 h of data) from 17 September to 28 October 2012 over Menorca. The temporal resolution is 1 h and a gliding average of 15 m was applied in the vertical. (b) Same as (a) but measured by BASIL over the 12-day time period from 0000 UTC on 17 October 2012 to 0000 UTC on 27 October 2012 during HyMeX. The temporal resolution is 5 min and a gliding average of 150 m was applied in the vertical. (c) same as (a) measured by ARTHUS collected between 11 and 19 February 2020 onboard the research vessel Maria S. Merian within the EUREC4A deployment. The temporal resolution is 10 s and a gliding average of 50 m was applied in the vertical. The black/white areas correspond to missing data due to the limitation of the detection system during the daytime. The black areas correspond to missing data due to the limitation of the detection system during the daytime or lidar system operation stoppage.

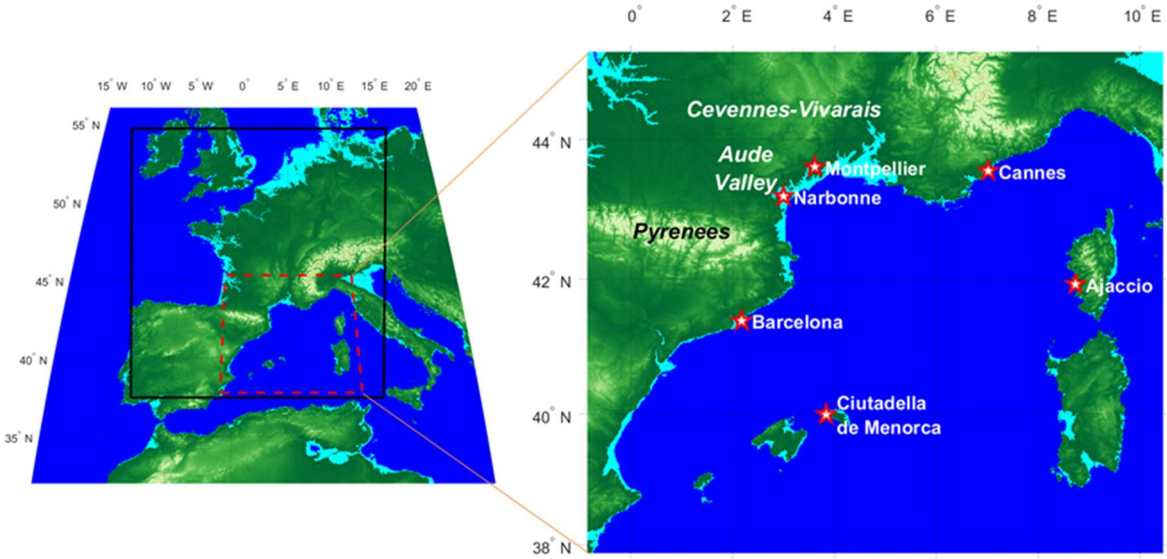

Figure 4: Left: Orography of the AROME-France domain (area delimited by the back contour). Right: zoom on the region of operation of the Raman Lidar Network with the location (city) of each lidar highlighted with red & white stars.

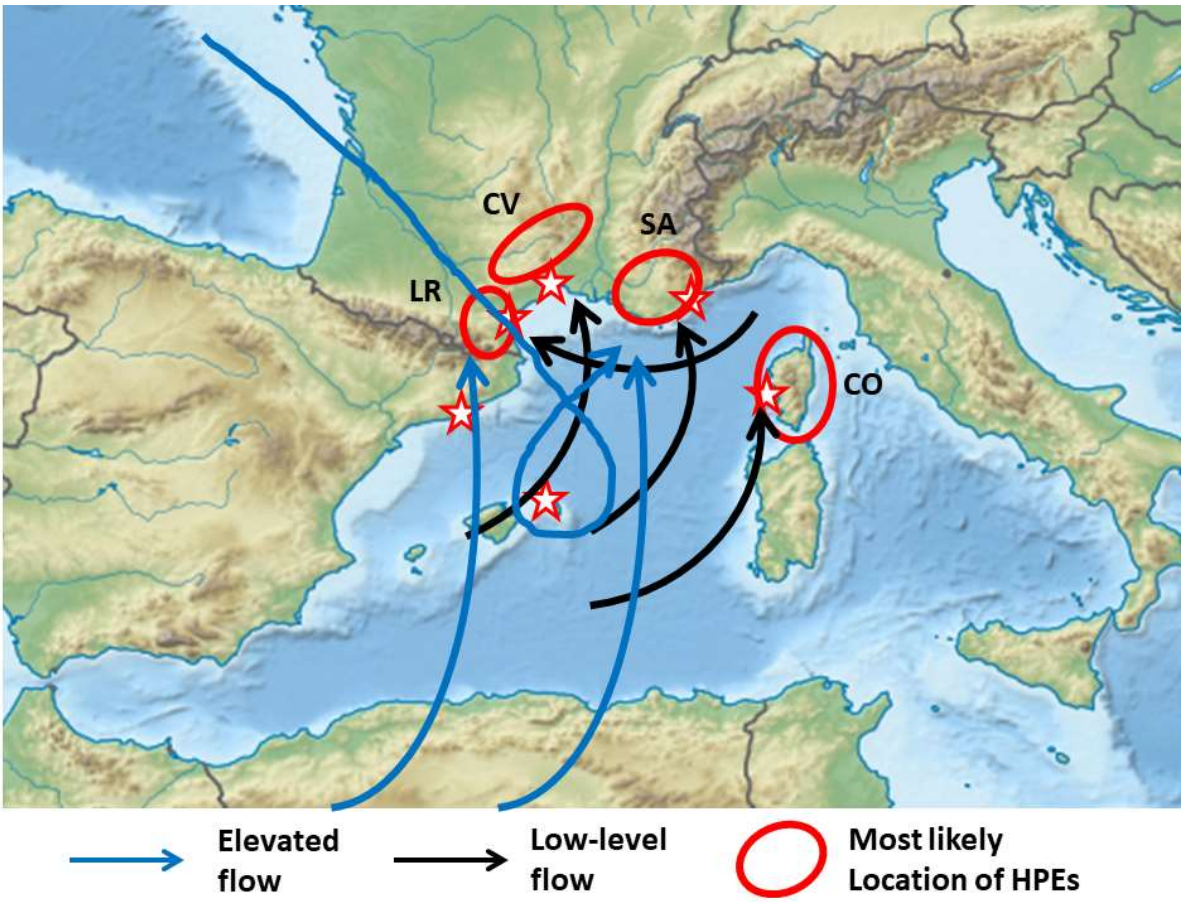

Figure 5: Regions most likely to be impacted by HPEs (red circles) together with main flow patterns in the low-levels (black arrows) and in altitude (2-4 km, blue arrows). LR is Languedoc-Roussillon, CV is Cévennes-Vivarais, SA is southern Alps and CO is Corsica.

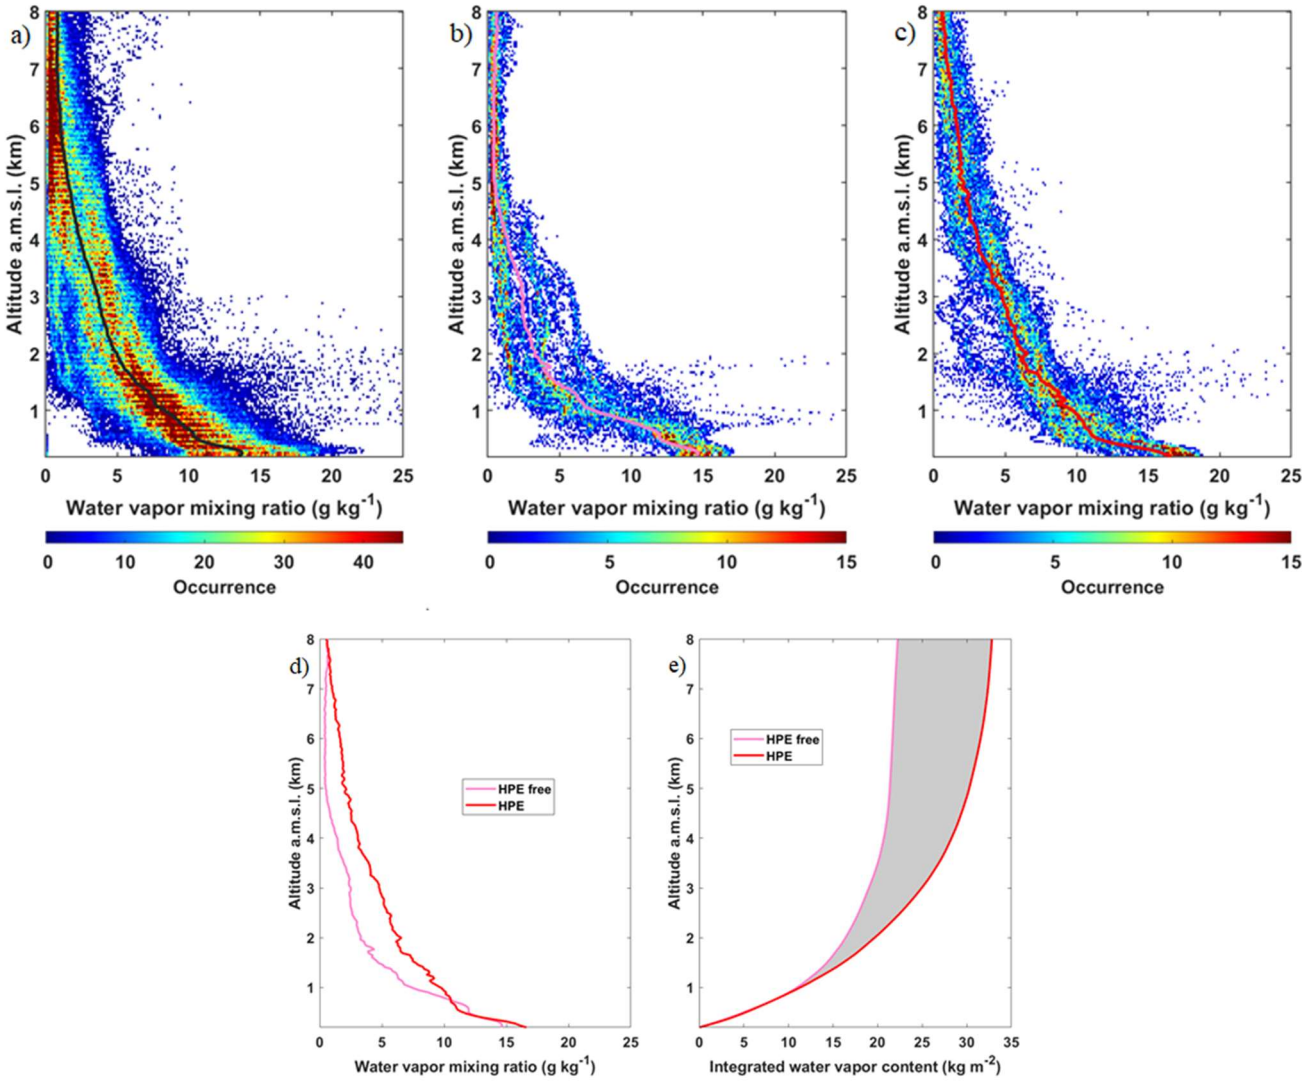

Figure 6:. (a) Density distribution of all WV vertical profiles acquired with WALI during the HyMeX SOP1 (see Figure 5a). The black solid line indicate the barycenter of the distribution at each altitude bin. The ocurrence of water vapor mixing ratio values is color code. (b) Same as (a), but for the profiles acquired in HPE-free conditions from 2 to 6 October 2012. The pink solid line indicate the barycenter of the distribution at each altitude bin. (c) Same as (b), profiles acquired in HPE conditions from 7 to 11 October 2012. The red solid line indicate the barycenter of the distribution at each altitude bin. (d) Average vertical distribution of WV mixing ratio as a function of altitude in the HPE-free case (pink solid line) and the HPE case (red solid line). (e) Integrated water vapour content as a function of altitude for the HPE-free case (pink solid line) and the HPE case (red solid line). The integrated content is computed at the integral of the lidar-derived specific humidity profiles from the ground upward. The shaded area highlights the difference between the HPE-free and HPE distribution.

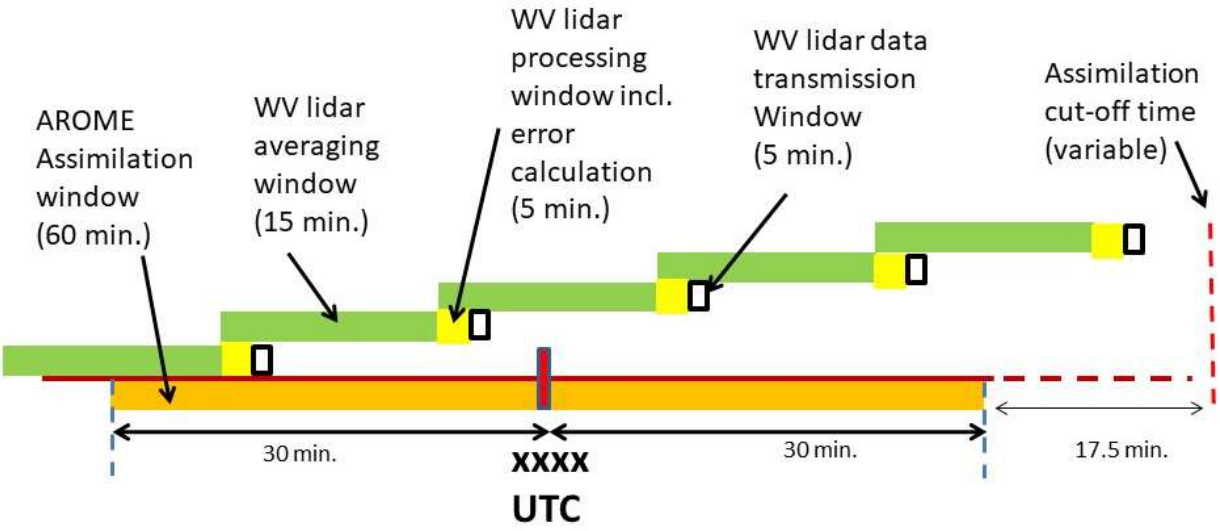

Figure 7: Timeline of the WV lidar data transmission sequence from the operating sites to Météo-France for assimilation of near-real time WV profiles in the AROME-France NWP system.
