The self-assembling properties of thermally-sensitive amphiphilic elastin-like multiblock recombinamers have been combined with the capacities of calcium phosphate binding of the SN<sub>A</sub>15 epitope inspired by the salivary protein statherin. In this regard, the interaction between calcium and phosphate ions was examined in the presence of two hybrid recombinamers. The first recombinamer comprised a simple amphiphilic diblock in which the SN<sub>A</sub>15 epitopes were combined, at the gene level, to the hydrophilic end. This recombinamer can self-assemble into nanoparticles that can control the transformation of amorphous calcium phosphate (ACP) into fibre-like hydroxyapatite structure. In the other recombinamer, the SN<sub>A</sub>15 domains are distributed along monomer chain, with the hydrophilic blocks being distributed amongst the hydrophobic ones. In this case, the resulting nanohybrid ACP/recombinamer organises into neuron-like structures. Thus, combining the amphiphilic elastin-like recombinamers to the SN<sub>A</sub>15 functionality is a powerful mean to tune the formation of different complex calcium phosphate nanostructures.

### 1. Introduction

The synthesis of self-assembled calcium phosphate hybrid structures represents a novel approach for the fabrication a new class of materials. In self-assembly processes, non-covalent cooperative interactions are responsible for the aggregation and formation of supramolecular structures with unique properties.<sup>1-3</sup> In the particular field of calcium phosphates, self-assembly represents a major tool for understanding bone mineralization and the basis to create new functional materials. In this process, organic molecules with different amphiphilic properties regulate the organization of different organic/inorganic hybrid structures, thus controlling the biomimetic mineralization process.<sup>1, 2, 4, 5</sup> They can be introduced as insoluble additive (templating approach) like is the case of Langmuir monolayers and self-assembled monolayers that are used to determine the functional group distance to nucleate a desired mineral phase or even to control the growth of particular polymorphs.<sup>4, 6-8</sup> Alternatively, organic molecules can also

be used as soluble additives imparting great influence on crystallization modulating the morphology, size and polymorph type of the crystal.<sup>4, 9, 10</sup> The ability of organic molecules to complex ions, self-aggregate or adsorb onto specific crystal surfaces are just some strategies through which soluble molecules control mineralization.

Various types of organic molecules have been used to investigate the organization of the organic/inorganic hybrid structures, to help understanding the mechanisms controlling the biomimetic mineralization processes.<sup>1, 2, 4, 5</sup> For example, self-assembled peptide-amphiphile can direct hydroxyapatite (HA) to form a composite material with an organization similar to that found for collagen fibrils and HA in bone.<sup>1, 2</sup> Furthermore, diblock copolymers can induce meso-skeleton formation of interconnected calcium phosphate nanofibers with a star/neuron-like morphology, although more complex nested forms can also be produced.<sup>2, 5</sup> Identical structures have also been generated using simpler organic molecules such as surfactants, sodium polyacrylate and poly(diallyldimethylammonium chloride).<sup>9</sup> Also, studies using dephosphorylated Fluorenylmethoxycarbonyl (Fmoc) tyrosine phosphate had demonstrated the capability of spontaneously forming fibers that could later be mineralized.<sup>11</sup>

Elastin-like polypeptides and, now-a-days, their recombinant versions, elastin-like recombinamers (ELRs) are a family of polypeptides inspired by natural elastin that can be used to control the biomimetic mineralization process.<sup>12</sup> They are composed of simple amino-acid

1 sequences (VPGXG)\* (see Table 1 for details on sample  
2 nomenclature), where X can be any natural or synthetic  
3 amino acid except proline.<sup>13-15</sup> In aqueous solution, ELRs  
4 exhibit an intrinsic inverse transition temperature ( $T_t$ ).  
5 Below  $T_t$ , the free chains remain disordered and have  
6 random coil conformations that are fully hydrated as a  
7 result of hydrophobic hydration. This hydration around  
8 hydrophobic moieties is ordered into cage-like or  
9 clathrate structures that are stabilized by hydrogen  
10 bonding. In contrast, above  $T_t$  the ELR backbone is  
11 dehydrated and can self-assemble into  $\beta$ -turn  
12 conformations.<sup>13-15</sup> In this structure, intra- and inter-chain  
13 hydrophobic contacts result in formation of a phase-  
14 separated state. The guest amino acid residue (X) can be  
15 varied to change the value of  $T_t$  and, consequently, the  
16 amphiphilic properties of the designed ELR block.<sup>13, 16</sup> For  
17 example, poly(VPGIG) exhibits a hydrophobic nature  
18 stemming from the presence of L-isoleucine (I) as guest.<sup>16</sup>  
19 <sup>17</sup> In contrast, poly(VPGEG) and poly(VPGKG) exhibit a  
20 hydrophilic nature due to the presence of L-glutamic (E)  
21 acid and L-lysine (K), respectively.<sup>16, 18</sup>

22 The above simple ELR-based blocks can be combined  
23 with each other to make amphiphilic ELRs that can self-  
24 assemble and generate different nanostructures.<sup>3, 19</sup> For  
25 example, the ELR E50I60 is composed of an I60 block  
26 ((VGIPG)<sub>60</sub>V) with a  $T_t$  of about 19 °C and an E50 block  
27 (MESLLP((VPGVG)<sub>2</sub>(VPGEG)(VPGVG)<sub>2</sub>))<sub>10</sub> whose estimated  
28  $T_t$  is higher than 100 °C at neutral pH.<sup>3, 18, 20</sup> The chains of  
29 this ELR can self-assemble into micelles in which the  
30 hydrophobic I60 blocks form the core and the hydrophilic  
31 E50 blocks the corona. In contrast, the ELR IK24  
32 (MESLLP(((VPGIG)<sub>2</sub>(VPGKG)(VPGIG)<sub>2</sub>)<sub>24</sub>V)) cannot form a  
33 micellar structure above its  $T_t$  of 31.5 °C.<sup>19</sup> The chain of  
34 this ELR is composed of hydrophobic (VPGIG)<sub>2</sub> and  
35 hydrophilic (VPGKG) blocks.<sup>19</sup>

36 Such biocompatible ELRs could be used as a  
37 regenerative material in various applications, such as  
38 bone regeneration, when recombined with a bioactive  
39 domain.<sup>12</sup> This domain could, for example, be the  
40 hydrated N-terminal 15-amino-acid residue of salivary  
41 statherin known as SN15 (DS<sub>p</sub>S<sub>p</sub>E EKFLRRIGRFG), or its  
42 analog SN<sub>A</sub>15 (DDDEEKFLRRIGRFG).<sup>21</sup> Due to their charge  
43 density and helical conformation, these proteins domains  
44 exhibit a high affinity for calcium phosphate and therefore  
45 high adsorption on the surface of HA.

46 The main goals of the present work were to study the  
47 influence of SN<sub>A</sub>15 on the behavior of calcium phosphate  
48 interaction when incorporated into ELR and to elucidate  
49 how the amphiphilic properties of these ELRs affect the  
50 calcium phosphate phases and morphologies generated.  
51 To this end, new hybrid recombinamer was designed,  
52 produced and characterized in which three SN<sub>A</sub>15  
53 domains were combined with the hydrophilic end of the  
54 ELR E50I60, thus resulting in the presence of SN<sub>A</sub>15 on the  
55 external surface of E50I60 micelles. The effect of this ELR  
56 on calcium phosphate formations was studied in parallel

57 with that of the ELR ((IK)2-SN<sub>A</sub>15-(IK)2)<sub>3</sub>, which has three  
58 SN<sub>A</sub>15 domains distributed along its monomer chain.

## 61 2. Materials and experimental methods

### 63 2.1. Recombinamer synthesis

64 The composition and length of monodisperse  
65 amphiphilic ELR molecule can be controlled using  
66 standard genetic engineering methods.<sup>22</sup> As such,  
67 sequential introduction of repetitive EL- or SN<sub>A</sub>15-  
68 polypeptide-coding gene segments was carried out using  
69 the recursive directional ligation technique to form fusion  
70 genes. This method requires the construction of coding  
71 gene segments flanked at both ends with non-palindromic  
72 restriction sites. In this work, the gene segments encoding  
73 each monomer were contained in a modified version of  
74 the cloning vector pDrive (Qiagen), known as pDAll, which  
75 is characterized by the engineering of two inverted Ear I  
76 and one Sap I restriction sites into the poly-linker region.  
77 Construction of the (SN<sub>A</sub>15)<sub>3</sub>E50I60 sequence was verified  
78 using agarose gel electrophoresis of the restriction  
79 fragments generated after enzymatic digestion and  
80 automated DNA sequencing. Selected genes were sub-  
81 cloned into a modified version of pET-25(+) expression  
82 vector and then transformed into *E. coli* strain BLR (DE3)  
83 star (Invitrogen).

### 85 2.2. ELR production and purification

86 Purification was performed by inverse temperature  
87 cycling using the following procedures.<sup>22</sup> After lysis of *E.*  
88 *coli* expression colonies, the denatured materials were  
89 removed by cold centrifugation (4 °C) at 15000 × g for 30  
90 min. After that, 1 M of NaCl was added to the soluble  
91 fraction and the mixture heated for 1 h at 40 °C.  
92 Centrifugation at 40 °C was performed, and the insoluble  
93 fraction was re-suspended in cold ultrapure water,  
94 followed by cold centrifugation. The soluble fraction was  
95 subjected to two additional cycles of heating with NaCl  
96 addition and cold re-suspension. Finally, the ELR was  
97 dialyzed in ultrapure water and the final pH of the  
98 solution adjusted to about 7.4, followed by lyophilization.  
99 The resulting (SN<sub>A</sub>15)<sub>3</sub>E50I60 was characterized by matrix-  
100 assisted laser desorption-ionization time-of-flight (MALDI-  
101 TOF) mass spectrometry, amino-acid analysis, nuclear  
102 magnetic resonance (NMR), attenuated total reflection  
103 infrared (ATR-IR) spectroscopy and differential scanning  
104 calorimetry (DSC).

### 106 2.3. MALDI-TOF mass Spectrometry

107 MALDI-TOF mass spectrometry was used to determine  
108 the molecular weight of ELRs. The matrix used for MALDI-  
109 TOF analysis was composed of 7.6 mg of 2,5-DHAP  
110 dissolved in 375  $\mu$ L of ethanol and mixed with 125  $\mu$ L of  
111 18 mg/mL C<sub>6</sub>H<sub>8</sub>O<sub>7</sub>·2NH<sub>3</sub> aqueous solution. Then, 1  $\mu$ L from  
112 this matrix was added to the MALDI plate along with 1  $\mu$ L  
113 ELR solution. The plate was dried in air and the mass

1 spectra collected using a Bruker autoflex speed  
2 instrument equipped with a nitrogen laser (337 nm)  
3 operating in the positive ion mode with delayed  
4 extraction.

#### 6 2.4. NMR spectroscopy

7 Proton nuclear magnetic resonance ( $^1\text{H}$  NMR)  
8 spectroscopy was performed using a 400-MR NMR  
9 spectrometer (400 MHz, Agilent Technologies). 15-20 mg  
10 of the purified ELR was dissolved in 600  $\mu\text{L}$  of deuterated  
11 dimethyl sulfoxide ( $\text{DMSO-d}_6$ ) and the spectrum  
12 measured at 25  $^\circ\text{C}$ . Chemical shifts ( $\delta$ ) are given in ppm.  
13 Data were processed using MestReNova software.  $\text{DMSO-}$   
14  $\text{d}_5$  peaks at  $\delta = 2.5$  ppm was used as internal reference for  
15 the  $^1\text{H}$  spectra.

#### 17 2.5. Amino acid Analysis

18 Samples were hydrolysed in 6 M HCl and 2% Phenol  
19 (30 min at 160  $^\circ\text{C}$ ) and evaporated under inert  
20 atmosphere. The solid residues were re-suspended in 1  
21 mL of 0.1 M HCl. Then, derivatizations with the OPA and  
22 FMOC chemistries were performed using an Agilent  
23 1329A auto-sampler as reported in literature.<sup>23</sup> The  
24 derivatized amino acids were analysed by HPLC with UV  
25 detection using an Agilent 1200 series variable  
26 wavelength detector equipped with a G1314B detector.

#### 28 2.6. ATR-IR Spectroscopy

29 ATR-IR analyses were conducted using a BRUKER  
30 TENSOR 27, USA spectrophotometer. Solid ELR samples  
31 were placed directly on the ATR crystal for measurement.  
32 For each spectrum, a 128-scan was collected with a  
33 resolution of 2  $\text{cm}^{-1}$  in the range 4000 to 600  $\text{cm}^{-1}$ .  
34 Spectral manipulations were performed using the OPUS  
35 (version 4.2) software (MATTSON INSTRUMENT, INC.).

#### 37 2.7. DSC

38 A Mettler Toledo 822e differential scanning  
39 calorimeter (DSC), with liquid-nitrogen cooler and  
40 calibrated with indium, was used to calculate the  $T_t$  of the  
41 ELRs synthesized. ELR samples were dissolved in ultrapure  
42 water at a concentration of 50 mg/mL at 4  $^\circ\text{C}$ . Then, 20  $\mu\text{L}$   
43 of ELR solution was placed in a 40  $\mu\text{L}$  sealed aluminum  
44 pan, and the same volume of ultrapure water was placed  
45 in the reference pan. Before the experiment, samples  
46 were held at 0  $^\circ\text{C}$  for 5 min and measurements were  
47 performed in the range 0 to 60  $^\circ\text{C}$  at a heating rate of 5  
48  $^\circ\text{C}/\text{min}$ .

#### 50 2.8. Circular dichroism (CD)

51 A Jasco J-815 spectropolarimeter (Jasco Inc., Easton,  
52 MD) under a constant nitrogen gas flow was used to  
53 obtain CD spectra for ELRs. Samples were dissolved in 0.5  
54 mM  $\text{CaCl}_2$  (pH  $\sim 7.4$ ) at 0.05 mg/mL, and filtered using a  
55 PVDF 0.45 $\mu\text{m}$  STE: R syringe filter at 4  $^\circ\text{C}$ . CD spectra were

56 recorded at 37  $^\circ\text{C}$  over the wavelength range 190-260 nm,  
57 using a 0.2-cm path length quartz cell, recording a point  
58 every 0.5 nm with a scan speed of 50 nm/min.

#### 60 2.9. Calcium phosphate precipitation in the presence of ELRs

61 When a solution of calcium cations is mixed with a  
62 solution of phosphate anions, calcium phosphate  
63 nucleation and crystallization can take place. To be able to  
64 investigate the effect of various ELRs on the reaction of  
65 calcium phosphate, the following procedure was  
66 performed. The first step was to dissolve ELR at the  
67 desired concentration in 10 mM solution of  $\text{CaCl}_2$  at 4  $^\circ\text{C}$ .  
68 The sample solution was then heated to 37  $^\circ\text{C}$  and kept at  
69 this temperature for least 15 min (pH 7.4) under  
70 continuous magnetic stirring. After that, an equivolume  
71 solution of 6 mM  $\text{Na}_2\text{HPO}_4$  at 37  $^\circ\text{C}$  (pH 7.4) was added to  
72 the solution to give a final Ca/P ratio of 1.67, similar to  
73 that found in the literature.<sup>6, 9</sup> The calcium phosphate  
74 precipitation was studied at final ELRs concentrations of 0,  
75 0.5, 1, 2, 3 and 4 mg/mL. All reagents used for preparation  
76 of calcium and phosphate solutions were obtained from  
77 Sigma Aldrich and used without further purification. The  
78 temperature was controlled during the reaction using  
79 thermo-jacketed vessels coupled to a thermostatic bath  
80 (Huber CC2).

81 The calcium phosphate reaction was monitored with  
82 the help of an electrical conductivity probe (Crison  
83 MM41). The initial time of reaction ( $t = 0$ ) was taken when  
84 the phosphate solution added to the mixture. All  
85 conductivity profiles were analyzed and the induction  
86 time, defined as the time taken for metastable transient  
87 phases to transform into more stable phases, was  
88 determined.<sup>9, 24</sup>

#### 90 2.10. X-ray diffraction (XRD):

91 The composition of calcium phosphate precipitated in  
92 the absence or presence of ELRs were analyzed by X-ray  
93 diffraction. Samples were isolated by centrifugation,  
94 washed two times using ultrapure water and dried at 37  
95  $^\circ\text{C}$ . The white precipitate was then ground in an agate  
96 mortar prior to XRD analysis. XRD patterns were recorded  
97 on a Bruker D8 Discover A 25 equipment using  $\text{CuK}\alpha$   
98 radiation ( $\lambda = 1.5406 \text{ \AA}$ ) and a silicon sample holder. The  
99 step size was 0.02 $^\circ$ . Crystallographic identification of the  
100 examined phases was compared with the PDF 01-072-  
101 1243.

#### 103 2.11. Energy dispersive X-ray spectroscopy (EDX):

104 The Ca/P ratio of the calcium phosphate precipitated  
105 after centrifugation, washing and drying, were  
106 determined by energy dispersive X-ray spectroscopy  
107 (EDAX Genesis with an Apollo SDD detector, 10 mm).

**Table 1.** Amino acid sequence of the ELRs.

ELR name	ELR amino acid sequence*	Mw (kDa)
E50I60	MESLLP[[(VPGVG) <sub>2</sub> (VPGEG)(VPGVG) <sub>2</sub> ] <sub>10</sub> ](VGIPG) <sub>60</sub> V	46999±19.96
(SN <sub>A</sub> 15) <sub>3</sub> E50I60	MESLLPV[DDDEEKFLRRIGRFG]3[[(VPGVG) <sub>2</sub> (VPGEG)(VPGVG) <sub>2</sub> ] <sub>10</sub> ](VGIPG) <sub>60</sub> V	52970 ±12
(IK)24	MESLLP[[(VPGIG) <sub>2</sub> (VPGKG)(VPGIG) <sub>2</sub> ] <sub>24</sub> V	51996.5±11.30

\* D= L-aspartic, E= L-glutamic, K= L-lysine, F= L-phenylalanine, L= L-leucine, R= L-arginine, I= L-isoleucine, G= Glycine, V= L-valine, P= L-proline, M= L-methionine and S= L-serine.

### 1 2.12. Transmission electron microscopy (TEM)

2 TEM specimens were prepared by soaking a 300 mesh  
3 carbon-coated copper grid in the required solution for the  
4 required time. The grid was then removed and blotted  
5 immediately to remove the excess of liquid, and air-dried.  
6 Electron microscopy and diffraction were performed using  
7 a JEOL-JEM 2200FS system operating at 200 kV and  
8 equipped with an energy dispersive X-ray (EDX) analysis  
9 detector. The microscope was equipped with an in-  
10 column  $\Omega$ -type energy filter. Zero-loss images were  
11 recorded to increase contrast. X-ray spectra were  
12 acquired in scanning transmission electron microscopy  
13 (STEM) mode using an Oxford INCA EDX system. The live  
14 counting time was 100 s.

## 16 3. Results and discussion

### 17 Hybrid elastin-like-statherin recombinamers

18 The amino acid sequence of the different constructs  
19 E50I60, (SN<sub>A</sub>15)<sub>3</sub>E50I60, IK24 and ((IK)2-SN<sub>A</sub>15-(IK)2)3  
20 are shown in Table 1. E50I60, (IK)24 and ((IK)2-SN<sub>A</sub>15-(IK)2)3  
21 were synthesized and characterized as reported  
22 previously in the literature.<sup>19, 20, 25</sup> The transition  
23 temperature ( $T_t$ ) of the ELR E50I60 was exploited to purify  
24 the whole (SN<sub>A</sub>15)<sub>3</sub>E50I60 hybrid molecule under water-  
25 based and mild conditions. The final (SN<sub>A</sub>15)<sub>3</sub>E50I60  
26 product was characterized by SDS-page analysis, MALDI-  
27 TOF mass spectrometry, <sup>1</sup>H NMR, amino-acid analysis and  
28 ATR-IR spectroscopy (Supplementary information: Figures  
29 S1-S4 and Table S1-S2), which proven the correctness and  
30 purity of the biosynthetic process in terms of sequence  
31 and molecular mass. DSC experiments were performed in  
32 order to check the  $T_t$  of the ELR (SN<sub>A</sub>15)<sub>3</sub>E50I60 (Figure  
33 S5).

34 As the secondary structure of polypeptides has a  
35 remarkable influence on controlling the mineralization  
36 process,<sup>4, 10, 26</sup> CD was used as a spectroscopic technique  
37 to study the conformation of ELRs shown in Table 1.  
38 Calcium phosphate interaction in the presence of these

39 ELRs was then examined by monitoring the electrical  
40 conductivity ( $\sigma$ ) as a function of time. The induction time  
41 ( $t_i$ ), defined as the time at which a stable solid phase  
42 starts to form, was also determined. The formed calcium  
43 phosphates were characterized by XRD. Moreover, the  
44 morphologies of the calcium phosphate species formed  
45 were observed by TEM and characterized by electron  
46 diffraction and EDX. To this end, the reaction conditions  
47 were chosen carefully to be able to visualize the  
48 amorphous phase transformations in an adequate time  
49 frame.

### 51 Circular dichroism spectroscopy (CD)

52 CD has been used to analyze the basic secondary  
53 structure of polypeptide,  $\alpha$ -helix,  $\beta$ -sheet,  $\beta$ -turns and  
54 random coils.<sup>27-30</sup> Figure 1 shows the CD spectra recorded  
55 for the ELRs, all of which exhibit one positive and two  
56 negative peaks. The negative peaks centered at 197, 199  
57 and 200.5 nm are attributed to the random coil  
58 conformations, whereas the negative peak centered at  
59 223 nm and the positive peak at 209-212 nm are assigned  
60 to type II  $\beta$ -turns.<sup>28-30</sup> The Mean Residual Ellipticity (MRE)  
61 of the characteristic random coil peak of these ELRs is  
62 higher than that found for an ideal random coil (-40000  
63 deg·cm<sup>2</sup>·dmol<sup>-1</sup>).<sup>29, 30</sup> This is due to the presence of  $\beta$ -turn  
64 conformations stemming from the hydrophobic (VPGIG)  
65 block.

66 Figure 1A shows that the center of the random coil  
67 peak is shifted from 197 to 199 nm, with its amplitude  
68 changing from -3670 to -3463 deg·cm<sup>2</sup>·dmol<sup>-1</sup> when SN<sub>A</sub>15  
69 is recombined with the E50I60 monomer chain. In  
70 addition, the amplitude of the  $\beta$ -turn peak alters from -  
71 2581 to -3019 deg·cm<sup>2</sup>·dmol<sup>-1</sup>. A similar behavior can be  
72 observed in Figure 1B for IK24 and ((IK)2-SN<sub>A</sub>15-(IK)2)3  
73 in which the characteristic random coil peaks are found at  
74 197 and 200.5 nm with MRE amplitudes of -6421 and -  
75 4436 deg·cm<sup>2</sup>·dmol<sup>-1</sup>, respectively. There is no shift in the  
76 amplitude of the  $\beta$ -turn peak can be seen.

**Figure 1.** CD of ELRs at 0.05 mg/mL dissolved in 0.5 mM CaCl<sub>2</sub> (37 °C), (A) E50I60 and (SN<sub>A</sub>15)<sub>3</sub>E50I60, and (B) IK24 and ((IK)<sub>2</sub>SN<sub>A</sub>15((IK)<sub>2</sub>)<sub>3</sub>.

## 1 Formation of nanofibre-like hydroxyapatite structure 2 controlled by (SN<sub>A</sub>15)<sub>3</sub>E50I60

3 Electrical conductivity measurements performed  
4 during the calcium phosphate reaction in the  
5 absence/presence of E50I60 and (SN<sub>A</sub>15)<sub>3</sub>E50I60 are  
6 shown in Figure 2A. The profiles presented clearly exhibit  
7 three regions after phosphate addition. Region I  
8 corresponds to the initial precipitation of a metastable  
9 calcium phosphate phase, which is an amorphous phase  
10 that is susceptible to rapid transformation (region II) into  
11 a secondary stable precipitate (region III).<sup>9, 24</sup> It can be  
12 seen from Figure 2B that E50I60 does not significantly  
13 affect the *I*<sub>t</sub>, which remains at about 5 min, even with  
14 increasing concentration. This value is similar to that  
15 obtained for the control sample in the absence of ELRs. In  
16 contrast, (SN<sub>A</sub>15)<sub>3</sub>E50I60 delays the secondary  
17 precipitation with a nearly constant *I*<sub>t</sub> of around 25 min.

18 The precipitates formed after *I*<sub>t</sub> (region III) were  
19 examined using XRD (Figure 2C) confirming the presence

20 of HA (PDF 01-072-1243). The peaks are broad accounting  
21 for the poorly crystalline nature of the precipitates. The  
22 Ca/P ratio of the precipitates in the presence of 2 mg/mL  
23 E50I60 and (SN<sub>A</sub>15)<sub>3</sub>E50I60 were 1.45 ± 0.02 and 1.46 ±  
24 0.02, respectively, and that of HA formed in the absence of  
25 ELRs was 1.45 ± 0.02. These ratios are assigned to calcium  
26 deficient HA.<sup>31-33</sup>

27 The morphologies and phases of the formed calcium  
28 phosphate after *I*<sub>t</sub> (region III) are shown in Figure 3. In the  
29 absence of ELRs, the formed calcium phosphate is mostly  
30 composed of plate-like crystals, as shown in Figure 3A.  
31 Moreover, the electron-diffraction pattern shown in the  
32 inset to the figure exhibits a crystal lattice corresponding  
33 to the HA phase consistent with the XRD results. The  
34 addition of E50I60 does not seem to significantly alter the  
35 morphology of the HA (Figure 3B), whereas a completely  
36 different structure consisting of polycrystalline nanofibre-  
37 like HA aggregates (Figure 3C) is formed in the presence of  
38 (SN<sub>A</sub>15)<sub>3</sub>E50I60.

**Figure 2.** (A) Electrical conductivity profiles measured by mixing 3 mL of 10 mM CaCl<sub>2</sub> and 3 mL of 6 mM Na<sub>2</sub>HPO<sub>4</sub> at 37 °C (pH 7.4) in the presence of E50I60 (red curve) and (SN<sub>A</sub>15)<sub>3</sub>E50I60 (blue curve) at 2 mg/mL. The conductivity profile (black curve) in the absence of these ELRs is included for comparison. (B) *I*<sub>t</sub> as a function of these ELR concentrations. Lines are drawn to allow the changes to be seen more clearly. (C) XRD patterns of the precipitates after *I*<sub>t</sub> (region III) in the presence of E50I60 (red curve) and (SN<sub>A</sub>15)<sub>3</sub>E50I60 (blue curve) at 2 mg/mL. The XRD pattern of the precipitate formed in the absence of ELRs (black curve) is included for comparison.

**Figure 3.** TEM showing the morphology of the calcium phosphate obtained after  $I_t$  and their corresponding electron-diffraction patterns: (A) in the absence of ELRs and in the presence of (B) 2 mg/mL E50I60 and (C) 2 mg/mL  $(\text{SN}_A15)_3\text{E50I60}$ . Some planes consistent with the HA crystal lattice can be observed in the electron-diffraction patterns (inset).

### 1 Formation of neuron-like morphologies controlled by ((IK)2- 2 $\text{SN}_A15$ -(IK)2)3

3 Figure 4A shows the electrical conductivity profiles for  
4 the mixed calcium phosphate solutions in the  
5 absence/presence of (IK)24 and ((IK)2- $\text{SN}_A15$ -(IK)2)3.  
6 Figure 4B shows that  $I_t$  is independent of the presence of  
7 the former ELR, remaining at about 5 min even upon  
8 increasing the concentration. In contrast, the latter ELR  
9 delays secondary precipitation with a steady,  
10 concentration-dependent, increase in  $I_t$  up to about 37  
11 min at 4 mg/mL. The XRD patterns (Figure 4C) of the  
12 precipitates formed in the absence/presence of (IK)24 and  
13 ((IK)2- $\text{SN}_A15$ -(IK)2)3 are assigned to poorly crystalline HA  
14 phase (PDF 01-072-1243). The Ca/P ratio determined by  
15 EDX in the presence of 2 mg/mL of (IK)24 and ((IK)2- $\text{SN}_A15$ -  
16 (IK)2)3 is  $1.43 \pm 0.02$  and  $1.47 \pm 0.08$  respectively, which is  
17 attributed to calcium deficient HA.<sup>31-33</sup>

18 Figure 5A shows the morphologies and phases of the  
19 calcium phosphate formed in the presence of IK24,  
20 confirming the formation of plate-like HA crystals similar  
21 to those observed in the control sample without ELRs. In  
22 contrast, for ((IK)2- $\text{SN}_A15$ -(IK)2)3 neuron-like structures  
23 were mostly observed (Figures 5C, 5D). The cores of these  
24 neurons were examined by EDX revealing the presence of  
25 calcium and phosphate with Ca/P  $\sim 1.14$  (Figures S6). At a  
26 concentration of 0.5 mg/mL, the neuron-like morphology  
27 has a core of about 40-50 nm and thin nanofilaments

28 about 5-10 nm in width and 150-200 nm in length. Upon  
29 increasing the concentration to 2 mg/mL, the filaments  
30 become shorter (about 100-150 nm) whereas the core  
31 becomes larger (about 90-120 nm), thus forming a  
32 mesostructured ACP/((IK)2- $\text{SN}_A15$ -(IK)2)3. High resolution  
33 TEM analyses demonstrate that the cores and filaments  
34 do not exhibit any crystallite formation. Electron-  
35 diffraction analyses of the neuron-like cores confirm their  
36 amorphous structure (inset of Figure 5C). This contrasts  
37 with the XRD patterns that indicate the presence of an  
38 additional phase: poorly crystalline HA. The presence of  
39 this phase is due to spontaneous precipitation and is not  
40 controlled by ((IK)2- $\text{SN}_A15$ -(IK)2)3.

41 Although the self-assembling process of hybrid  
42 biomaterials in the present work has the merit of mild  
43 reaction conditions, the main disadvantage associated to  
44 this synthesis route is precisely the low temperature and  
45 the mild reaction conditions that often leads to  
46 precipitation of secondary phases (i.e. HA). Many  
47 alternative routes can be used to overcome this drawback  
48 (hydrothermal, sonochemical or combustion techniques  
49 among others) but at the cost of sacrificing the mild  
50 reaction conditions inherent to biomimetic synthesis  
51 routes.<sup>32, 33</sup> However, in spite of the presence of HA for  
52 ((IK)2- $\text{SN}_A15$ -(IK)2)3, the effect of this recombinamer in  
53 the modulation of calcium phosphate precipitation is  
54 clear.

55

**Figure 4.** (A) Electrical conductivity profiles measured by mixing 3 mL of 10 mM  $\text{CaCl}_2$  and 3 mL of 6 mM  $\text{Na}_2\text{HPO}_4$  at 37 °C (pH 7.4) in the presence of IK24 (red curve) and ((IK)2-SNA<sub>15</sub>-((IK)2)3 (blue curve) at 2 mg/mL. The conductivity profile (black curve) in the absence of these ELRs is included for comparison. (B)  $I_t$  as a function of IK24 and ((IK)2-SNA<sub>15</sub>-((IK)2)3 concentration. Lines are drawn to allow the changes to be seen more clearly. (C) XRD patterns of the precipitates after  $I_t$  (region III) in the presence of IK24 (red curve) and ((IK)2-SNA<sub>15</sub>-((IK)2)3 (blue curve) at 2 mg/mL. The XRD pattern of the precipitate formed in the absence of ELRs (black curve) is included for comparison.

**Figure 5.** TEM showing the morphology of the calcium phosphate obtained after  $I_t$  (region III) and their corresponding electron-diffraction patterns: (A) in the absence of ELRs and in the presence of (B) 0.5 mg/mL ((IK)24, (C) 0.5 mg/mL ((IK)2-SNA<sub>15</sub>-((IK)2)3, and (D) 2 mg/mL ((IK)2-SNA<sub>15</sub>-((IK)2)3.

### 1 Mechanisms controlling calcium phosphate formation 2 under the influence of self-assembling ELRs as organic 3 additives

4  
5 Organic additives are well known to modulate  
6 amorphous-to-crystalline calcium phosphate  
7 transformations and to influence the stabilization of

8 amorphous phases.<sup>1, 2, 5, 6, 9, 34, 35</sup> This can be achieved by  
9 the presence of locally highly charged areas on the  
10 organic molecules that can induce electrostatic and  
11 hydrogen-bonding interactions with the calcium and  
12 phosphate ions during the mineralization process. The  
13 hydrophobic constituent of these organic matrixes can act  
14 as an architectural framework, whereas the hydrophilic

1 constituents are directly involved in controlling mineral  
 2 nucleation and growth. Due to the strong binding  
 3 interactions between organic and inorganic phases,  
 4 aggregates composed of hybrid primary particles with  
 5 metastable ACP can be generated.<sup>1, 2, 5, 6, 9, 34, 35</sup> This  
 6 metastable ACP can slowly crystallize inside these  
 7 aggregates. For example, in the present work, the organic  
 8 additives (SN<sub>A</sub>15)<sub>3</sub>E50I60 and ((IK)2-SN<sub>A</sub>15-(IK)2)<sub>3</sub> can  
 9 delay I<sub>t</sub>, whereas the other organic additives E50I60 and  
 10 ((IK)24 cannot. Consequently, SN<sub>A</sub>15 has a marked ability  
 11 to control the mineralization process of calcium  
 12 phosphate. Moreover, two different morphologies,  
 13 namely fibre- and neuron-like structures, can be  
 14 generated. These unexpected results can be interpreted  
 15 on the basis of the interaction mechanisms that control  
 16 ACP/ELR hybrid aggregate formation as a function of the  
 17 amphiphilic properties of the ELR.

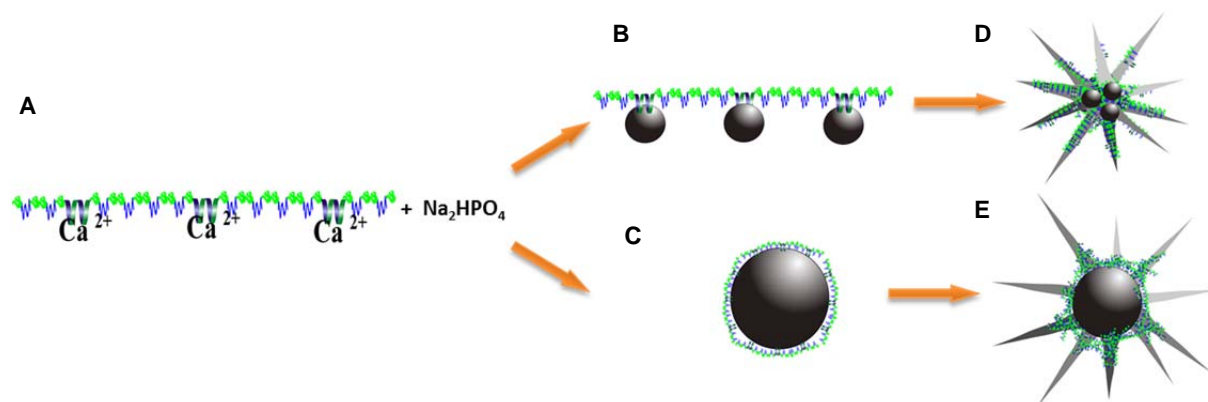

18 In the absence of ELRs, the mixing of calcium and  
 19 phosphate solutions results in the formation of  
 20 aggregated ACP spheres prior to I<sub>t</sub> (Figure S7A), which are  
 21 subsequently transformed into plate-like crystals after I<sub>t</sub>  
 22 (Figure 3A). In contrast, a dispersed hybrid spherical  
 23 structure is formed in the presence of (SN<sub>A</sub>15)<sub>3</sub>E50I60 and  
 24 ((IK)2-SN<sub>A</sub>15-(IK)2)<sub>3</sub> (Figures S7B, S7C). In consequence,  
 25 flocculation bridging is prevented and the transformation  
 26 dynamics are severely reduced. The formation  
 27 mechanisms of these hybrid structures, and their  
 28 transformation into different nanostructures, can be  
 29 explained in detail using the schematic representations  
 30 shown in Figures 6 and 7. Thus, (SN<sub>A</sub>15)<sub>3</sub>E50I60 can self-  
 31 assemble into a micellar structure in which the (SN<sub>A</sub>15)<sub>3</sub>

32 domains are exposed on the outer surface (Figure 6A).  
 33 This could explain why I<sub>t</sub> remains practically the same  
 34 regardless of (SN<sub>A</sub>15)<sub>3</sub>E50I60 concentration, thus meaning  
 35 that calcium ions are readily sequestered by the (SN<sub>A</sub>15)<sub>3</sub>  
 36 and influencing any subsequent precipitation. The high  
 37 density of negative charge concentrated on the micelle  
 38 surface captures calcium ions, thereby generating a  
 39 positive charge on the surface. Once the phosphate  
 40 solution is added (before I<sub>t</sub>), there are two possible  
 41 pathways that the reaction mechanism can follow to  
 42 generate the hybrid (SN<sub>A</sub>15)<sub>3</sub>E50I60/ACP structure. Firstly,  
 43 the positively charged surface of the micelle (Figure 6A)  
 44 can bind negatively charged phosphate groups and then,  
 45 in turn, additional calcium ions, etc., thus resulting in the  
 46 formation of ACP (Figure 6B). Secondly, (SN<sub>A</sub>15)<sub>3</sub>E50I60  
 47 micelles can be adsorbed onto the ACP surfaces formed,  
 48 once the phosphate solution is added, via (SN<sub>A</sub>15)<sub>3</sub> (Figure  
 49 6C). This would result in the formation of a dispersed  
 50 hybrid spherical structure, as shown in supporting  
 51 information Figure S6B. SN<sub>A</sub>15 plays an important role in  
 52 controlling the ACP transformation in both pathways,  
 53 which can lead to preferential growth inhibition for  
 54 different crystal phases by lowering their surface energy.<sup>2</sup>  
 55 The hydrophilic (SN<sub>A</sub>15)<sub>3</sub>E50 segments are involved in  
 56 controlling the transformation of ACP spheres into fibre-  
 57 like HA (Figures 6D, 6E), whereas the I60 blocks can self-  
 58 assemble hydrophobically, thus leading to the mesoscale  
 59 organization of these fibre-like HA structures *in situ* and  
 60 generating ordered aggregates (Figure 3C).  
 61 (SN<sub>A</sub>15)<sub>3</sub>E50I60 can therefore inhibit plate-like crystals  
 62 and regulate fibre-like structure of HA.

**Figure 6.** Schematic representation of the possible pathways the reaction mechanism can follow once phosphate solution is added to (SN<sub>A</sub>15)<sub>3</sub>E50I60 micelles dissolved in CaCl<sub>2</sub> solution. (SN<sub>A</sub>15)<sub>3</sub> is represented by , whereas green and blue colors represent the I60 and E50 blocks, respectively. ACPs are represented by dark spheres.

**Figure 7.** Schematic representation of the possible pathways the reaction mechanism can follow after addition of phosphate solution to a solution of ((IK)2-SNA<sub>15</sub>-(IK)2)3 and calcium ions. SNA<sub>15</sub> is represented by , whereas green and blue color represent the (VPGIG) and (VPGKG) blocks, respectively. ACPs are represented by the dark spheres.

1 The hydrophilic (VPGKG) blocks in ((IK)2-SNA<sub>15</sub>-(IK)2)3  
 2 are distributed amongst the hydrophobic (VPGIG) blocks.  
 3 Although this ELR structure cannot form micelles in  
 4 aqueous solution, calcium ions can accumulate on the  
 5 SNA<sub>15</sub> moieties distributed along the monomer chain  
 6 (Figure 7A). Upon addition of phosphate anions, there are  
 7 also two possible pathways the reaction mechanism can  
 8 follow, before I<sub>v</sub>, to generate a ((IK)2-SNA<sub>15</sub>-(IK)2)3/ACP  
 9 hybrid structure. Firstly, the positive surface of SNA<sub>15</sub>  
 10 (Figure 7A) can be screened by negative phosphate  
 11 groups followed by additional calcium ions, etc., thus  
 12 meaning that ACP could be formed (Figure 7B). In  
 13 contrast, the hydrophobic segments ((VPGIG) block) tend  
 14 to aggregate to minimize their surface area available to  
 15 the solvent and become shielded from the hydration layer  
 16 of kosmotropic ions.<sup>36, 37</sup> Secondly, ((IK)2-SNA<sub>15</sub>-(IK)2)3  
 17 can adsorb to the ACP surfaces formed, once the  
 18 phosphate solution is added, via SNA<sub>15</sub> (Figure 7C). In  
 19 both possible pathways, the hydrophobic moieties can  
 20 have a marked influence as regards to obstructing the  
 21 transport of ions to ACP clusters<sup>9, 35</sup>, thus preventing their  
 22 flocculation bridging (Figure S7C) and inhibiting the  
 23 transformation of ACP into a crystalline phase. The  
 24 hydrophilic moieties are excluded from the hydrophobic  
 25 one and can be separated when ((IK)2-SNA<sub>15</sub>-(IK)2)3-  
 26 mineral interactions become strong enough to disrupt and  
 27 push aside. After I<sub>v</sub>, a cooperative growth process gives  
 28 rise to a high anisotropy of nano-hybrid filaments, thus  
 29 generating the ((IK)2-SNA<sub>15</sub>-(IK)2)3/ACP neuron-like  
 30 morphology (Figures 5C, 5D, 7D, 7E). Moreover, the core  
 31 of these neurons increases in size with ((IK)2-SNA<sub>15</sub>-  
 32 (IK)2)3 concentration because of the increasing number of  
 33 hydrophobic moieties.

34 In light of the above, it can be suggested that, instead  
 35 of transformation of ACP into a fibre-like HA, similar to  
 36 the case of (SNA<sub>15</sub>)<sub>3</sub>E50I60, formation of an  
 37 organic/inorganic hybrid material composed of  
 38 amorphous micellar precursors is followed by a secondary  
 39 nucleation of nano-hybrid filaments after I<sub>v</sub>, similar to the  
 40 case of ((IK)2-SNA<sub>15</sub>-(IK)2)3.

41 The morphologies and phases of the generated  
 42 calcium phosphate under control of the amphiphilic  
 43 properties of ELRs in this work are in agreement with  
 44 previous findings whereby the biomimetic mineralization  
 45 process controlled by proteins tends to result in unfolded  
 46 structures, e.g. random coils, due to their interaction  
 47 motifs, rather than folded structures, e.g. β-turn, β-sheet,  
 48 and α-helix.<sup>10, 26</sup> For example, the β-turn conformation  
 49 found in (SNA<sub>15</sub>)<sub>3</sub>E50I60 is buried in the core of the  
 50 micellar structure and, in consequence, has no control  
 51 over calcium phosphate mineralization, whereas the  
 52 random coils are included to guide SNA<sub>15</sub> during fibre-like  
 53 HA formation. In contrast, the β-turn conformations  
 54 found in ((IK)2-SNA<sub>15</sub>-(IK)2)3 are included to control the  
 55 mineralization process that gives rise to organization of  
 56 ACP/((IK)2-SNA<sub>15</sub>-(IK)2)3 nanohybrid materials with a  
 57 neuron-like structure. In other words, the secondary  
 58 structure of polypeptides is associated with the hydration  
 59 layer found around their monomer chains, with the  
 60 random coils being more hydrated than the other  
 61 secondary structures (β-turn, β-sheet, and α-helix) and  
 62 playing an important role in ACP transformation.<sup>10, 26, 38</sup>  
 63 This means that the third component of bone, namely  
 64 water molecules, plays an important role in structuring  
 65 and organizing apatite crystals, as demonstrated  
 66 previously in the literature.<sup>38</sup>

67 Most of the works that have been published using  
 68 ELRs in combination with the statherin domain have  
 69 mainly focused on their synthesis<sup>19, 20, 25</sup> and *in vitro*  
 70 behaviour.<sup>12, 39-41</sup> *In vitro* studies on ELR membranes with  
 71 various epitopes and/or surface topographies have been  
 72 conducted to assess their potential for dental and  
 73 orthopaedic applications.<sup>12, 39, 40</sup> In addition,  
 74 biomineralization experiments have also been performed  
 75 on silk-like recombinamers (SS15m) combined with the  
 76 carboxyl terminal domain of dentin matrix protein 1  
 77 (CDMP1), which is a well-known sequence reported to  
 78 influence mineralization.<sup>42</sup> Besides those studies, up to  
 79 now, there was no clear evidence on fundamental aspects  
 80 such as the effect of statherin in the ELRs and how the

1 distribution of the statherin domain within the ELR  
2 backbone could affect biomineralization.

3 This study provides valuable information about the  
4 role of ELRs containing SN<sub>A</sub>15, which could be used as  
5 multifunctional materials for various applications. For  
6 instance, their ability to control the mineralization process  
7 could allow them to be used to modulate bone mineral  
8 density and treat various bone diseases.<sup>43-45</sup> Thus,  
9 (SN<sub>A</sub>15)<sub>3</sub>E50I60 or ((IK)2-SN<sub>A</sub>15-(IK)2)<sub>3</sub> nanostructures  
10 could be used as drug nano-carriers for bone cancer  
11 treatments. In the case of (SN<sub>A</sub>15)<sub>3</sub>E50I60, hydrophobic  
12 drugs could be carried by its hydrophobic core of I60  
13 blocks, whereas the hydrophilic block (SN<sub>A</sub>15)<sub>3</sub>E50 could  
14 be used to control the mineralization process. Moreover,  
15 as ((IK)2-SN<sub>A</sub>15-(IK)2)<sub>3</sub> controls the formation of neuron-  
16 like hybrid structures, it could interact with hydrophilic  
17 drugs to form organized nanostructures. In addition,  
18 ((IK)2-SN<sub>A</sub>15-(IK)2)<sub>3</sub> could be used to stabilize  
19 labile/metastable phases and form a neuron-like  
20 structure, and the resulting filaments could be used to  
21 impart topographical and even biological cues to trigger  
22 various cellular events. For example, they could be  
23 introduced as a complementary component in an  
24 extracellular matrix to induce the ingrowth of vascular  
25 and bone-forming cells.<sup>46, 47</sup>

## 26 Conclusions

27 The control of calcium phosphate nanostructures  
28 formations by the hybrid elastin-like-statherin  
29 recombinamers (SN<sub>A</sub>15)<sub>3</sub>E50I60 and ((IK)2-SN<sub>A</sub>15-(IK)2)<sub>3</sub>  
30 depends on two main parameters. Firstly, it depends on  
31 the presence of a high local charge on their surface that  
32 can delay the I<sub>t</sub>. (SN<sub>A</sub>15)<sub>3</sub>E50I60 can delay the secondary  
33 precipitation of calcium phosphate with a constant I<sub>t</sub> at  
34 increasing concentration, whereas ((IK)2-SN<sub>A</sub>15-(IK)2)<sub>3</sub>  
35 can delay secondary precipitation with a steady  
36 concentration-dependent increase in I<sub>t</sub>. These striking  
37 differences in the effects of ELRs on I<sub>t</sub> have been  
38 interpreted as being dependent on the second main  
39 parameter, namely the amphiphilic properties of ELRs.  
40 Thus, (SN<sub>A</sub>15)<sub>3</sub>E50I60 can self-assemble to form  
41 nanoparticles in which the (SN<sub>A</sub>15)<sub>3</sub> domains are exposed  
42 on the outer surface. This means that the (SN<sub>A</sub>15)<sub>3</sub>E50  
43 block can control the transformation of ACP into a fibre-  
44 like HA structure, whereas the I60 blocks can self-  
45 assemble hydrophobically, thus leading to the mesoscale  
46 organization of these fibre-like HA structures *in situ* and  
47 generating ordered aggregates. In contrast, the  
48 hydrophilic (VPGKG) blocks are distributed amongst the  
49 hydrophobic (VPGIG) blocks in ((IK)2-SN<sub>A</sub>15-(IK)2)<sub>3</sub>, thus  
50 hindering the transformation of ACP into a crystalline  
51 phase. In this case, a neuron-like morphology of ((IK)2-  
52 SN<sub>A</sub>15-(IK)2)<sub>3</sub>/ACP with high anisotropy nano-hybrid  
53 filaments is generated. In conclusion, the amphiphilic  
54 properties of thermally-sensitive amphiphilic elastin-like  
55 multiblock recombinamers play an important role in

56 tuning the SN<sub>A</sub>15 bioactive domain and, in consequence,  
57 the calcium phosphate morphologies generated.
